Also of current interest is the SIBTEST procedure proposed by Shealy and Stout [25]. Shealy and Stout [25] note that this procedure can be considered an extension of the standardization procedure of Dorans and Kulick [6]. Its primary advantages over the standardization index are that it does not require large samples and that it provides a test of significance. It is conceptually model-based but non-parametric. The procedure begins by identifying a ‘valid subtest’ on which conditioning is based and a ‘studied subtest’, which may be a single item or group of items. The SIBTEST test statistic is based on the weighted sum of differences in the average scores of reference and focal group members with the same valid subtest true score. Shealy and Stout [25] show that if there are group differences in the distribution of the trait, matching on observed scores does not properly match on the trait, so they base matching instead on the predicted valid subtest true score, given observed valid subtest score. Shealy and Stout [25] derive a test statistic that is approximately normally distributed. Like the standardization and MH procedures, the SIBTEST procedure is designed to detect only uniform DIF. Li and Stout [14] modified SIBTEST to produce a test sensitive to nonuniform DIF. Jiang and Stout [11] offered a modification of the SIBTEST procedure to improve Type I error control and reduce estimation bias. The advantages of the SIBTEST procedure are its strong theoretical basis, relative ease of calculation, and effect size measure.

Extensions of all of the DIF procedures described above have been developed for use with polytomous models. Cohen, Kim, and Baker [4] developed an extension of the IRT area method and an accompanying test statistic and provided a generalization of Lord’s D^2 . IRT likelihood ratio tests are also readily extended to polytomous item response models [2, 13]. Rogers and Swaminathan [24] described logistic regression models for unordered and ordered polytomous responses and provided chi-square test statistics with degrees of freedom equal to the number of item parameters being compared. Zwick, Donoghue,

and Grima [30] gave an extension of the standardization procedure for ordered polytomous responses based on comparison of expected responses to the item; Zwick and Thayer [31] derived the standard error for this statistic. Zwick et al. [30] also presented generalized MH and Mantel statistics for unordered and ordered polytomous responses, respectively; the test statistic in the unordered case is distributed as a chi-square with degrees of freedom equal to one less than the number of response categories, while the test statistic in the ordered case is a chi-square statistic with one degree of freedom. These authors also provide an effect size measure for the ordered case. Chang, Mazzeo, and Roussos [3] presented an extension of the SIBTEST procedure for polytomous responses based on conditional comparison of expected scores on the studied item or subtest. Potenza and Dorans [20] provided a framework for classifying and evaluating DIF procedures for polytomous responses.

Investigations of DIF remain an important aspect of all measurement applications; however, current research efforts focus more on interpretations of DIF than on development of new indices.

Direct and Indirect Effects

Suppose that a researcher wants to study the impact of an independent variable X on a dependent variable Y . To keep things simple, imagine that X has two conditions, a treatment condition and a control condition, and, ideally (in order to make causal inferences a bit easier), that participants have been randomly assigned to one or the other of these conditions. In this context, the total effect will be defined as the effect of X on Y , and can be, for instance, estimated in the context of a linear regression model (see **Multiple Linear Regression**) as the following:

$$Y = \beta_{01} + \tau X + \varepsilon_1 \quad (1)$$

It should be noted that in some situations, for instance when Y is a latent construct, the X to Y relationship would be estimated using **structural equation modeling**. In (1), the slope τ thus represents the total effect of X on Y . This relationship can be schematized as in Figure 1. The estimate of τ in a given sample is often labeled c .

It is possible that the researcher will be interested in finding the mechanism responsible for this $X - Y$ relationship [1–3]. The researcher may hypothesize that a third variable is partially responsible for the observed effect. The question will then be: Does a part of the total effect go through a third variable, often called a mediator (or an intervening variable)? Is there an indirect effect of X on Y going through Me (as Mediator)? (see **Mediation**) This three-variable relationship can be schematized as in Figure 2. In

Figure 1 Total effect

Figure 2 Direct and indirect effects

this context, the indirect effect will be the product of the path going from X to Me and the path going from Me to Y . Frequently, the former will be called α in the population or a in the sample, and, the latter, β in the population and b in the sample. This indirect effect will then be $\alpha * \beta$ in the population and $a * b$ in the sample. In regression terms, the two following models will be run in order to estimate both α and β :

$$Me = \beta_{02} + \alpha X + \varepsilon_2 \quad (2)$$

$$Y = \beta_{03} + \tau' X + \beta Me + \varepsilon_3 \quad (3)$$

As can be seen in (3), and in line with Figure 2, the β path is the effect of Me on Y controlling for X . In this same equation, we estimate the $X:Y$ partial relationship once Me has been controlled. This is equivalent to the remaining (or residual) effect of X on Y once the part of this relationship that goes through Me has been removed. This coefficient is frequently labeled τ' (or c' in the sample). This is the direct effect of X on Y . It should be noted that the term ‘direct’ must be understood in relative terms, given that there may be other mediators that potentially explain this direct effect. Hence, in the case of two mediators Me_1 and Me_2 , the direct effect would be the residual effect of X on Y not explained by either Me_1 or Me_2 .

As a summary, so far we have seen that:

$$\text{Total effect} = \tau$$

$$\text{Indirect effect} = \alpha\beta, \quad (4)$$

and

$$\text{Direct effect} = \tau'. \quad (5)$$

Furthermore, it can be shown, not surprisingly, that the total effect (τ) is equal to the direct effect (τ') plus the indirect effect ($\alpha\beta$) (e.g., [5]). In other words:

$$\tau = \tau' + \alpha\beta. \quad (6)$$

It follows that:

$$\tau - \tau' = \alpha\beta. \quad (7)$$

From this last equation, it can be seen that the indirect effect can be estimated either by $\alpha\beta$ or $\tau - \tau'$, the change in effect of X on Y when controlling and not controlling for Me . This is of importance because, if mediation is at stake, it should be the

2 Direct and Indirect Effects

case that $|\tau| > |\tau'|$. Hence, the magnitude of the $X - Y$ relationship should decrease once the mediator is controlled. The total effect must be of a higher magnitude than the direct effect. It could happen, however, that $|\tau| < |\tau'|$. If it is the case, the third variable is not a mediator but a suppressor (e.g., [4]). In this case, this third variable does not reflect a possible mechanism for the relationship between X and Y , but, on the contrary, hides a portion of this relationship. When the third variable is a suppressor, the relationship between X and Y is stronger once this third variable is controlled.

Extension to Models with More Than One Mediator

As suggested above, in some cases, multiple mediator models could be tested. Then, there will be multiple possible indirect effects. For instance, in a model like the one presented in Figure 3, there will be an indirect effect through Me_1 (i.e., $\alpha_1\beta_1$) and another one through Me_2 (i.e., $\alpha_2\beta_2$). In such a situation, it is still possible to calculate an overall indirect effect taking into account both the indirect effect through Me_1 and through Me_2 . This one will be the sum of $\alpha_1\beta_1$ and $\alpha_2\beta_2$ (or a_1b_1 and a_2b_2 in terms of their sample estimates). It also follows that:

$$\tau - \tau' = \alpha_1\beta_1 + \alpha_2\beta_2. \quad (8)$$

Illustration

Two researchers conducted a study with only female participants [6]. They first showed, in line with the

Figure 3 Two indirect effects

so-called stereotype threat literature (e.g., [7]), that these female participants performed less well at a math test in a condition making salient their gender (see [6] for details on the procedure) than in a control condition. The test of this effect of condition on math performance is, thus, the *total effect*. The linear regression conducted on these data revealed a standardized estimate of $c = -0.42$ (in this illustration, we used the standardized estimates simply because these are what these authors reported in their article. The same algebra would apply with the unstandardized estimates). Next, these authors wanted to demonstrate that this difference in math performance was due to a decrease in working memory in the condition where female gender was made salient. In other words, they wanted to show that working memory mediated the condition effect. In order to do so, they conducted two additional regression analyses: The first one, regressing a working memory measure on condition, and the second, regressing math performance on both condition and working memory (i.e., the mediator). The first one gives us the path from condition to working memory ($a = -0.52$); the second one gives us the path from the mediator to the math performance controlling for condition ($b = 0.58$) and the path from condition to math controlling for working memory ($c' = -0.12$). So, in this illustration, the *indirect effect* is given by $a * b = -0.30$ and the *direct effect* is $c' = -0.12$. This example also illustrates that, as stated before, $c - c' = ab$, so that $-0.42 - (-0.12) = -0.52 * 0.58$. The total effect, -0.42 is, thus, due to two components, the direct effect (-0.12) and the indirect effect (-0.30).

Direct Maximum Likelihood Estimation

Many widely used statistical procedures (e.g., structural equation modeling, multilevel modeling) rely on **maximum likelihood estimation** (ML) to obtain estimates of model parameters. The basic goal of ML is to identify the population parameter values most likely to have produced a particular sample of data. The fit of the data to a set of parameter values is gauged by the *log likelihood* (see **Maximum Likelihood Estimation**), a value that quantifies the relative probability of a particular sample, given that the data originated from a normally-distributed population with a mean vector and covariance matrix, μ and Σ , respectively. Estimation usually requires the use of iterative algorithms that ‘try out’ different values for the unknown parameters, ideally converging on the parameter values that maximize the log likelihood.

ML estimation is ideally suited for analyses of incomplete datasets, and requires less stringent assumptions about the missingness mechanism than traditional methods such as listwise deletion. So-called *direct maximum likelihood* (direct ML; also known as *full information maximum likelihood*) is widely available in commercial software packages, and the number of models to which this estimator can be applied is growing rapidly. To better appreciate the benefits of direct ML estimation, it is necessary to understand Rubin’s [4] taxonomy of missing data mechanisms. A more detailed treatment of missing data can be found elsewhere in this volume (see **Missing Data; Dropouts in Longitudinal Data**), but a brief overview is provided here.

Data are said to be *missing completely at random* (MCAR) when missingness on a variable Y is unrelated to other variables as well as the values of Y itself (i.e., the observed data are essentially a random sample of the hypothetically complete data). *Missing at random* (MAR) is less stringent in the sense that missingness on Y is related to another observed variable, X , but is still unrelated to the values of Y . For example, suppose a counseling psychologist is investigating the relationship between perceived social support and depression, and finds that individuals with high levels of support are more likely to have missing values on the depression inventory (e.g., they

prematurely terminate therapy because of their perceived support from others). Finally, data are *missing not at random* (MNAR) when missing values on Y are related to the values of Y itself. Returning to the previous example, suppose that individuals with low levels of depression are more likely to have missing values on the depression inventory, even after controlling for social support (e.g., they prematurely terminate therapy because they don’t feel depressed).

Although behavioral researchers are unlikely to have explicit knowledge of the missing data mechanism (only MCAR can be empirically tested), the theoretical implications of Rubin’s [4] taxonomy are important. Rubin showed that unbiased and efficient parameter estimates could be obtained from likelihood-based estimation (e.g., direct ML, multiple imputations) under MAR. If one views the missing data mechanism as a largely untestable assumption, the implication is that ML estimation is more ‘robust’ in the sense that unbiased and efficient estimates can be obtained under MCAR and MAR, whereas traditional approaches generally produce unbiased estimates under MCAR only.

We will explore the basic principles of direct ML estimation using the dataset in Table 1. The data consist of 10 scores from a depression inventory and measure of perceived social support, and an MAR mechanism was simulated by deleting depression scores for the three cases having the highest levels of social support. Additionally, the social support variable was randomly deleted for a single case.

As described previously, the ML log likelihood quantifies the relative probability of the data, given a normally distributed population with an unknown

Table 1 Hypothetical depression and perceived social support data

Complete		Missing

6	22	?	22

2 Direct Maximum Likelihood Estimation

mean vector and covariance matrix, μ and Σ , respectively. ML estimation proceeds by ‘trying out’ values for μ and Σ in an attempt to identify the estimates that maximize the log likelihood. In the case of direct ML, each case’s contribution to the log likelihood is computed using the observed data for that case. Assuming multivariate normality, case i ’s contribution to the sample log likelihood is given by

$$\log L_i = K_i - \frac{1}{2} \log |\Sigma_i| - \frac{1}{2} (\mathbf{y}_i - \boldsymbol{\mu}_i)' \Sigma_i^{-1} (\mathbf{y}_i - \boldsymbol{\mu}_i), \quad (1)$$

where $\mathbf{y}_i$ is the vector of raw data, $\boldsymbol{\mu}_i$ is the vector of population means, Σ_i is the population covariance matrix, and K_i is a constant that depends on the number of observed values for case i . The sample log likelihood is subsequently obtained by summing over the N cases, as shown in (2).

$$\log L = K - \frac{1}{2} \sum_{i=1}^N \log |\Sigma_i| - \frac{1}{2} \sum_{i=1}^N (\mathbf{y}_i - \boldsymbol{\mu}_i)' \Sigma_i^{-1} (\mathbf{y}_i - \boldsymbol{\mu}_i). \quad (2)$$

The case subscript i implies that the size and content of the arrays differ according to the missing data pattern for each case. To illustrate, let us return to the data in Table 1. Notice that there are three missing data patterns: six cases have complete data, a single case is missing the social support score (Y_1), and three cases have missing values on the depression variable (Y_2). The contribution to the log likelihood for each of the six complete cases is computed as follows:

$$\begin{aligned} \log L_i &= K_i - \frac{1}{2} \log \begin{vmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{21} & \sigma_{22} \end{vmatrix} - \frac{1}{2} \left(\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} - \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} \right)' \\ &\quad \times \begin{bmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{21} & \sigma_{22} \end{bmatrix}^{-1} \left(\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} - \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} \right) \end{aligned} \quad (3)$$

For cases with missing data, the rows and columns of the arrays that correspond to the missing values are removed. For example, the arrays for the three cases with missing depression scores (Y_2) would include only y_1 , μ_1 , and σ_{11}^2 . Substituting these quantities into (1), the contribution to the log likelihood for each of these three cases is computed as

$$\log L_i = K_i - \frac{1}{2} \log |\sigma_{11}| - \frac{1}{2} (y_i - \mu_1)'$$

Table 2 Maximum likelihood parameter estimates

Variable	Estimate		
	Complete	Direct ML	Listwise
Mean			
Support	13.00	13.32	10.00
Depression	15.00	15.12	17.33
Variance			
Support	29.00	30.99	15.00
Depression	40.80	44.00	43.56
Covariance			
Support/Depression	-19.90	-18.22	-10.00

$$[\sigma_{11}]^{-1} (y_i - \mu_1) \quad (4)$$

In a similar vein, the log likelihood for the case with a missing social support score (Y_1) is computed using y_2 , μ_2 , and σ_2^2 .

To further illustrate, direct ML estimates of μ and Σ are given in Table 2. For comparative purposes, μ and Σ were also estimated following a listwise deletion of cases ($n = 6$). Notice that the direct ML estimates are quite similar to those of the complete data, but the listwise deletion estimates are fairly distorted. These results are consistent with theoretical expectations, given that the data are MAR (for depression scores, missingness is solely due to the level of social support). Moreover, there is a straightforward conceptual explanation for these results. Because the two variables are negatively correlated ($r = -0.58$), the listwise deletion of cases effectively truncates the marginal distributions of both variables (e.g., low depression scores are systematically removed, as are high support scores). In contrast, direct ML utilizes all observed data during estimation. Although it may not be immediately obvious from the previous equations, cases with incomplete data are, in fact, contributing to the estimation of all parameters. Although depression scores are missing for three cases, the inclusion of their support scores in the log likelihood informs the choice of depression parameters via the linear relationship between social support and depression.

As mentioned previously, ML estimation requires the use of iterative computational algorithms. One such approach, the *EM algorithm* (see **Maximum Likelihood Estimation**), was originally proposed as a method for obtaining ML estimates of μ and Σ

with incomplete data [1], but has since been adapted to complete-data estimation problems as well (e.g., **hierarchical linear models**; [3]). EM is an iterative procedure that repeatedly cycles between two steps. The process begins with initial estimates of μ and Σ , which can be obtained via any number of methods (e.g., listwise deletion). The purpose of the *E*, or *expectation*, step is to obtain the sufficient statistics required to compute μ and Σ (i.e., the variable sums and sums of products) in the subsequent *M* step. The complete cases simply contribute their observed data to these sufficient statistics, but missing *Y*s are replaced by predicted scores from a regression equation (e.g., a missing Y_1 value is replaced with the predicted score from a regression of Y_1 on Y_2 , Y_3 , and Y_4 , and a residual variance term is added to restore uncertainty to the imputed value). The *M*, or *maximization*, step uses standard formulae to compute the updated covariance matrix and mean vector using the sufficient statistics from the previous *E* step. This updated covariance matrix is passed to the next *E* step, and is used to generate new expectations for the missing values. The two EM steps are repeated until the difference between covariance matrices in adjacent *M* steps becomes trivially small, or falls below some *convergence criterion*.

The previous examples have illustrated the estimation of μ and Σ using direct ML. It is important to

note that a wide variety of linear models (e.g., regression, structural equation models, multilevel models) can be estimated using direct ML, and direct ML estimation has recently been adapted to nonlinear models as well (e.g., logistic regression implemented in the Mplus software package). Finally, when provided with the option, it is important that direct ML standard errors be estimated using the observed, rather than expected, **information matrix** (a matrix that is a function of the second derivatives of the log likelihood function), as the latter may produce biased standard errors [2].

Directed Alternatives in Testing

A common statistical testing situation is the consideration of a null hypothesis, which specifies that the means of populations are the same (or are homogeneous). For example, three different types of diet plans may be independently administered to three samples from populations of obese individuals of similar composition. The data consist of the amount of weight loss for each individual in the study. In such a case, the typical alternative is that the true 3 average (mean) weight losses for the populations are not the same. Such an alternative would be regarded as a nonrestricted alternative or one which has parameters, in a sense, in every direction. On the other hand, suppose one diet consisted of taking an innocuous pill (placebo), a second diet plan involved calorie reduction plus a bonafide diet pill, and a third diet regimen included everything in the second diet plan plus counseling. The null hypothesis is still that the true average weight loss is the same for the three diet plans, but a more realistic and more useful alternative is that the average weight loss is nondecreasing as we vary from the first to second to third diet plan. Such an alternative would be a directed alternative of the simple order type. Formally, if μ_i , $i = 1, 2, 3$ represents the true mean weight loss for diets 1, 2, and 3 respectively, the null hypothesis is $H : \mu_1 = \mu_2 = \mu_3$. The unrestricted alternative denoted by K_U is all parameter points except those in H . A directed alternative called the *simple order alternative* is $K_{S0} : \mu_1 \leq \mu_2 \leq \mu_3$, but not $\mu_1 = \mu_2 = \mu_3$.

The advantage of posing a directed alternative when it is appropriate to do so is that the appropriate statistical procedure has a much greater ability to detect such an alternative. In statistical jargon, this means that the power of the test for the restricted alternative can be decidedly greater than the **power** for the test of K_U .

When the directed alternative is simple order and normality assumptions for the data are reasonable, likelihood ratio tests (LRTs) can be recommended (see **Maximum Likelihood Estimation**). These are outlined in [6, Chapter 2]. This reference also contains a table on p. 95 from which one can measure the huge gains in power by subscribing to a test suitable

for the simple order alternative. Robertson, Wright, and Dykstra [6] also offer tests for the simple order alternative for binomial, multinomial, and Poisson data (see **Catalogue of Probability Density Functions**). Usually, large samples are required in these latter cases. For small samples and discrete data, the method of directed vertex peeling, DVP, as outlined in [2], is effective. See Example 4.1 of that reference for details. For nonparametric models, one can use rank test methodology as given by [1].

Another directed alternative commonly encountered in practical situations is the tree order alternative. Such an alternative is often appropriate when comparing k different treatment regimens with a control. Formally, if μ_i denotes the true mean for the i th treatment, $i = 1, \dots, k$, and μ_0 denotes the true mean for the control then the tree order alternative is $K_T : \mu_i - \mu_0 \geq 0, i = 1, \dots, k$, with strict inequality for some i .

For the simple order directed alternative, the LRTs can unhesitatedly be recommended. For the tree order directed alternative, a variety of tests have different types of advantageous properties. Dunnett [5] proposes a test for normal data with precise critical values. Cohen and Sackrowitz [3] recommend both a modification of Dunnett's test and a second test procedure with desirable monotonicity properties. That same reference contains a test appropriate for the nonparametric case. The DVP methodology is appropriate for discrete data and small sample sizes.

A third type of directed alternative that is important and frequently encountered is stochastic ordering. We describe this alternative for a $2 \times k$ **contingency table** with ordered categories. The rows of the table correspond to, say, control and treatment, whereas the columns of the table correspond to ordered responses to treatment. An example is a 2×3 table where the first row represents a placebo treatment and the second row represents an active treatment. The three columns represent respectively, no improvement, slight improvement, and substantial improvement.

The 2×3 table has cell frequencies as follows in Table 1:

Table 1

	No Improvement	Slight Improvement	Substantial Improvement	
Placebo	X_1	X_2	X_3	n_1
Treatment	Y_1	Y_2	Y_3	n_2

2 Directed Alternatives in Testing

Table 2

	No Improvement	Slight Improvement	Substantial Improvement
Placebo	p_1	p_2	p_3
Treatment	q_1	q_2	q_3

Here, X_1 , for example represents the number of n_1 individuals who received the placebo and had no improvement. The corresponding table of probabilities is as follows in Table 2:

Here, for example, p_1 represents the probability of having no improvement given the placebo was taken. Also $p_1 + p_2 + p_3 = q_1 + q_2 + q_3 = 1$.

The null hypothesis of interest is that the placebo probability distribution is the same as the treatment distribution. That is $H : p_i = q_i, i = 1, \dots, k$. The directed alternative is $K_{ST} : \sum_{j=1}^i p_j \geq \sum_{j=1}^i q_j, i = 1, \dots, k$, with at least one inequality. Thus, for $k = 3$, $K_{ST} : p_1 \geq q_1, p_1 + p_2 \geq q_1 + q_2$, with at least one strict inequality. The idea behind this directed alternative is that the probability distribution for the treatment population is more heavily concentrated on the higher-ordered categories.

To test H versus K_{ST} in a $2 \times k$ table, the methodology called *directed chi-square* is recommended. This methodology appears in [4]. One can simply input the data of a $2 \times k$ table into the following website: <http://stat.rutgers.edu/~madigan/dvp.html>. A conditional P value is quickly provided, which can be used to accept or reject H .

Some concluding and cautionary remarks are needed. We have offered three types of directed alternatives. There are many others. An excellent compilation of such alternatives is offered in [6].

By specifying a directed alternative, great gains in the power of the testing procedures are realized.

However, one needs to be confident, based on the practicality of the problem or based on past experience that the directed alternative is appropriate. Equally important is the correct specification of the null hypothesis. In specifying a null and a directed alternative, oftentimes many parameters in the original space are ignored. Recall in our first example, $H : \mu_1 = \mu_2 = \mu_3, K_{SO} : \mu_1 \leq \mu_2 \leq \mu_3$. Here, parameter points where $\mu_1 > \mu_2 > \mu_3$ are ignored. One should be confident that those parameter points that are left out can safely be ignored. Should the ignored parameters be relevant, the advantage of using a directed alternative is considerably diminished.

Direction of Causation Models

In the behavioral sciences, experimental manipulation is often not an option when investigating direction of causation (DOC) and so alternative statistical approaches are needed. Longitudinal or two-wave data designs (*see Longitudinal Designs in Genetic Research*), while potentially informative, are not without their disadvantages. In addition to the cost and time required for data collection, these include stringent methodological requirements (*see* [3, 6]). When only cross-sectional data are available, a novel approach is to model direction of causation on the basis of pairs of relatives, such as twins measured on a single occasion (*see Twin Designs*) [1, 3, 6].

The pattern of cross-twin cross-trait correlations can, under certain conditions, falsify strong hypotheses about the direction of causation, provided several

assumptions are satisfied (*see* [6]). One of these is that twin pair correlations are different between target variables, which is critical, because the power to detect DOC will be greatest when the target variables have very different modes of inheritance [3].

Figure 1 provides an illustrative example of DOC modeling based on cross-sectional data. Let us assume that variable A is best explained by shared (C) and nonshared (E) environmental effects, while variable B is best explained by additive genetic (A), dominant genetic (D), and nonshared (E) environment effects (*see ACE Model*). Under the “A causes B” hypothesis (a), the cross-twin cross-trait correlation (i.e., A_{t1} to B_{t2} or A_{t2} to B_{t1}) is $c_{AS}^2 i_B$ for MZ and DZ twin pairs alike. However, under the ‘B causes A’ hypothesis (b), the cross-twin cross-trait correlation would be $(a_{BS}^2 + d_{BS}^2) i_A$ for MZ and $(1/2 a_{BS}^2 + 1/4 d_{BS}^2) i_A$ for DZ twin pairs. It is apparent that if variables A and B have identical modes of inheritance, then the cross-twin cross-trait correlations will be equivalent for MZ and DZ twin

Figure 1 Unidirectional causation hypotheses between two variables A and B measured on a pair of twins. (a) Trait A causes Trait B and (b) Trait B causes Trait A. The figure also includes the expected cross-twin cross-trait correlations for MZ and DZ twins under each unidirectional hypothesis. Example based on simplified model of causes of twin pair resemblance in Neale and Cardon [5] and is also reproduced from Gillespie and colleagues [2]

2 Direction of Causation Models

pairs alike, regardless of the direction of causation, and the power to detect the direction of causation will vanish.

Neale and colleagues [7] have modeled direction of causation on the basis of the cross-sectional data between symptoms of depression and parenting, as measured by the dimensions of Care and Overprotection from the Parental Bonding Instrument [8]. They found that models that specified parental rearing as the cause of depression (parenting $\rightarrow$ depression) fitted the data significantly better than did a model that specified depression as causing

parental rearing behavior (depression $\rightarrow$ parenting). Yet, when a term for **measurement error** (omission of which is known to produce biased estimates of the causal parameters [5]) was included, the fit of the ‘parenting $\rightarrow$ depression’ model improved, but no longer explained the data as parsimoniously as a common additive genetic effects model (*see Additive Genetic Variance*) alone (i.e., implying indirect causation).

Measurement error greatly reduces the statistical **power** for resolving alternative causal hypotheses [3]. One remedy is to model DOC using multiple

Table 1 Results of fitting direction of causation models to the psychological distress and parenting variables. Reproduced from Gillespie and colleagues [2]

Model	Goodness of fit					
	χ^2	<i>df</i>	$\Delta\chi^2$	Δdf	<i>p</i>	<i>AIC</i>
Full bivariate	141.65	105				−68.35

Results based on 944 female MZ twin pairs and 595 DZ twin pairs aged 18 to 45.

^aDistress as measured by three indicators: depression, anxiety, and somatic distress.

^bParenting as measured by three indicators: coldness, overprotection, and autonomy.

* $p < .05$, ** $p < .01$, *** $p < .001$.

Figure 2 The best-fitting unidirectional causation model for the psychological distress and PBI parenting dimensions with standardized variance components (double-headed arrows) and standardized path coefficients. Circles represent sources of latent additive genetic (A), shared (C), and nonshared (E) environmental variance. Ellipses represent common pathways psychological distress and parenting. Reproduced from Gillespie and colleagues [2]

indicators [3–5]. This method assumes that measurement error occurs, not at the latent variable level but at the level of the indicator variables, and is uncorrelated across the indicator variables [5]. Gillespie and colleagues [2] have used this approach to model the direction of causation between multiple indicators of parenting and psychological distress. Model-fitting results are shown in Table 1.

The ‘parenting → distress’ model, as illustrated in Figure 2, provided the most parsimonious fit to the data. Unfortunately, there was insufficient statistical power to reject a full bivariate model. Therefore, it is possible that the parenting and psychological distress measures were correlated because of shared genetic or environmental effects (bivariate model), or simply arose via a reciprocal interaction between parental recollections and psychological distress. Despite this limitation, the chief advantage of this model-fitting approach is that it provides a clear means of rejecting the ‘distress → parenting’ and ‘no causation’ models, because these models deteriorated significantly from the full bivariate model. The correlations between the parenting scores and distress measures could not be explained by the hypothesis that memories of parenting were altered by symptoms of psychological distress.

Despite enthusiasm in the twin and behavior genetic communities, DOC modeling has received little attention in the psychological literature, which is a shame because it can prove exceedingly useful in illuminating the relationship between psychological constructs. However, as stressed by Duffy and Martin [1], these methods are not infallible or invariably informative, and generally require

judgment on the part of the user as to their interpretation.

Discriminant Analysis

There are many data analysis methods that involve multiple response variables, one of which is discriminant analysis. This analysis method was initiated by **Sir Ronald A. Fisher** in the 1930s in the context of classifying a plant into one of two species using four flower measurements as predictor scores. It is the context of classification/prediction that researchers in the natural sciences (e.g., genetics, biology) have associated discriminant analysis. In the behavioral sciences, however, applied researchers have typically associated discriminant analysis with the study of group differences. This latter association appears to have been initiated by methodologists at Harvard University in the 1950s. (See [1, pp. 25–26] for a little more detail on the history of discriminant analysis and *see also* **History of Discrimination and Clustering**.)

The typical design that might suggest the use of discriminant analysis involves two or more (say, k) groups of analysis units – or, subjects, such as students. A collection of two or more (say, p) response variable scores is available for each unit. One research question with such a design is: Are the k groups different with respect to means on the p outcome variables? (Or, equivalently, does the grouping variable have an effect on the collection of p outcome variables?) To answer this question, the typical analysis is **multivariate analysis of variance (MANOVA)**. Assuming that the answer to this research question is ‘yes,’ then one proceeds to describing the group differences – or, the effect(s) of the grouping variable. To address the description, one uses *descriptive discriminant analysis* (DDA). A second research question with the above design is: How well can group membership be predicted using scores on the p response variables? To answer this question, one would use *predictive discriminant analysis* (PDA). It should be noted that in DDA the response variables are *outcome* variables, while in PDA the response variables are *predictor* variables.

Description of Grouping-variable Effects

To repeat, the basic design considered here involves k groups of analysis units and p outcome variables. It is assumed at the outset that the collection of p outcome variables constitutes some type of ‘system.’

That is, the whole collection, or subsets, somehow ‘hang together’ in some substantive or theoretical sense. For an example, consider Data Set B in [1, p. 278]. The grouping variable is post-high-school education with levels: teacher college ($n_1 = 89$ students), vocational school ($n_2 = 75$), business or technical school ($n_3 = 78$), and university ($n_4 = 200$). The $N = 442$ students – the analysis units – were randomly selected from a nationwide stratified sample of nearly 26 000 eleventh-grade students. The $p = 15$ outcome variables are as follows.

Cognitive:

Literature information (LINFO),
Social Science information (SINFO),
English proficiency (EPROF),
Mathematics reasoning (MRSNG),
Visualization in three dimensions (VTDIM),
Mathematics information (MINFO),
Clerical-perceptual speed (CPSPD),

Interest:

Physical science (PSINT),
Literary-linguistic (LLINT),
Business management (BMINT),
Computation (CMINT),
Skilled trade (TRINT),

Temperament:

Sociability (SOCBL),
Impulsiveness (IMPLS),
Mature personality (MATRP).

(Whether or not these 15 outcome variables constitute a single ‘system’ is a judgment call.)

For this data set, the primary research question is: Are the $k = 4$ groups different with respect to the means on the $p = 15$ variables? To address this question, a MANOVA is conducted – assuming data conditions are satisfactory (see [6]). The MANOVA (omnibus) null hypothesis,

$$H_0 : \mu_1 = \mu_2 = \mu_3 = \mu_4, \quad (1)$$

(μ_j denotes the vector of 15 means for the j th population) may be tested using the Wilks lambda (Λ) criterion (*see* **Multivariate Analysis of Variance**), which is transformed to an F statistic – see [1, pp. 183–185]. For Data Set B, $\Lambda \doteq 0.5696$, $F(45, 1260.4) \doteq 5.841$, $P \doteq .0001$ and η_{adj}^2 . With these results, it is reasonable to reject H_0 , and conclude that the four group mean vectors are statistically different. Now the more interesting research question

2 Discriminant Analysis

is: Different with respect to what? (Or, on *what* does the grouping variable have an effect?) Here is where DDA comes into play.

DDA is used to determine what outcome variable *constructs* underlie the resultant group differences. The identification of the constructs is based on what are called *linear discriminant functions* (LDFs). The LDFs are linear combinations (or, composites) of the p outcome variables. (A linear combination/composite is a sum of products of variables and respective ‘weights.’) Derivation of the LDF weights is based on a mathematical method called an *eigen-analysis* (see [1, pp. 207–208]). This analysis yields numbers called **eigenvalues**. The number of eigenvalues is, in an LDF context, the minimum of p and $k - 1$, say, m . For Data Set B, $m = \min(15, 3) = 3$. With each eigenvalue is associated an **eigenvector**, numerical elements of which are the LDF weights. So, for Data Set B, there are three sets of weights (i.e., three LDFs) for the 15 outcome variables. The first LDF is defined by

$$Z_1 = 0.54Y_1 + 0.59Y_2 + \dots + 0.49Y_{15}. \quad (2)$$

The first set of LDF weights is mathematically derived so as to maximize, for the data on hand, the (canonical) correlation between Z_1 and the grouping variable (see **Canonical Correlation Analysis**). Weights for the two succeeding LDFs are determined so as to maximize, for the data on hand, the correlation between the linear combination/composite and the grouping variable that is, successively, independent of the preceding correlation.

Even though there are, for Data Set B, $m = 3$ LDFs, not all three need be retained for interpreting the resultant group differences. Determination of the ‘LDF space dimension’ may be done in two ways (see [1, pp. 211–214]). One way is to conduct three statistical tests:

- H_{01} : no separation on any dimension,
- H_{02} : separation on at most one dimension, and
- H_{03} : separation on at most two dimensions.

(Note that these are NOT hypotheses for significance of *individual* LDFs.) For Data Set B, results of the three tests are: $F_1(45, 1260.4) \doteq 5.84$, $P_1 \doteq 0.0001$; $F_2(28, 850) \doteq 1.57$, $P_2 \doteq 0.0304$ and $F_3(13, 426) \doteq 0.73$, $P_3 \doteq 0.7290$. On the basis of these results, *at most* two LDFs should be retained. The second way to address the dimension issue is a

proportion-of-variance approach. Each derived eigenvalue is a squared (canonical) correlation (between the grouping variable and the linear combination of the outcome variables), and, thus, reflects a proportion of shared variance. There is a shared-variance proportion associated with each LDF. For Data Set B, the proportions are: LDF₁, 0.849; LDF₂, 0.119; and LDF₃, 0.032. From this numerical information it may be concluded, again, that *at most* two LDFs need be retained.

Once the number of LDFs to be retained for interpretation purposes is determined, it may be helpful to get a ‘picture’ of the results. This may be accomplished by constructing an *LDF plot*. This plot is based on outcome variable means for each group on each LDF. For Data Set B and for LDF₁, the group 1 mean vector value is determined, from (1), to be

$$\bar{Z}_1 = 0.54\bar{Y}_1 + 0.59\bar{Y}_2 + \dots + 0.49\bar{Y}_{15} \doteq -0.94 \quad (3)$$

The group 1 mean vector (i.e., *centroid*) used with LDF₂ yields an approximate value of -0.21 . The two centroids for group 2, for group 3, and for group 4 are similarly calculated. The proximity of the group centroids is reflected in the LDF plot. (The typical plot used is that with the LDF axes at a right angle.) With the four groups in Data Set B, each of the four plotted points reflects the two LDF means. The two-dimensional plot for Data Set B is given in Figure 1. By projecting the centroid points, – for example, $(-0.94, -0.21)$ – onto the respective axes, one gets a general idea of group separation that may be attributed to each LDF. From Figure 1, it appears

Figure 1 Plot of group centroids for Data Set B

that LDF_1 may account for separation of G_4 on one hand versus G_1 , G_2 , and G_3 on the other. Also, it may be concluded that LDF_2 may account for separation of G_2 versus G_1 , G_3 , and G_4 . The latter separation may not appear to be as clear-cut as that associated with LDF_1 .

All this said and done, the researcher proceeds to making a substantive interpretation of the two retained LDFs. To accomplish this, one determines the correlations between each of the two LDFs and each of the 15 outcome variables. Thus, there are two sets of *structure r*'s, 15 in each set (see **Canonical Correlation Analysis**). The 'high' values are given in Table 1. The *structure r*'s for LDF_1 indicate that the difference of university students versus teacher college, vocational school, and business or technical school students may be attributed to the 'construct' of skill capability in mathematics, social science, and literature, along with maturity and interest in physical science. (It is left to the reader to arrive at a more succinct and concise 'name' for the construct reflected by LDF_1 .) The second construct is a 'combination' of mathematics reasoning and 3D visualization. (It should be recognized that researcher judgment is needed to determine the number of LDFs to retain, as well as to name them.) It is these constructs that describe/explain the group differences found via the MANOVA and illustrated with the LDF plot discussed above. The constructs may, alternatively, be viewed as on what the grouping variable has an effect.

It may be of further interest to the researcher to determine an 'ordering' of the outcome variables. This interest may also be viewed as determining the 'relative importance' of the outcome variables. Now there are two ways of viewing the variable ordering/relative importance issue. One way pertains to an ordering with respect to differences between/among

the groups. This ordering may be determined by conducting *all-but-one-variable MANOVAs*. With the above example, this would result in 15 14-variable analyses. What are examined, then, are the 15 14-variable MANOVA F values, and comparing each with the F value yielded by the overall 15-variable MANOVA. The variable not in the 14-variable subset that yields the largest F -value drop, relative to the 15-variable F value, is considered the most important variable with respect to the contribution to group differences. The remaining 14 variables would be similarly ordered using, of course, some research judgment – there usually would be some rank ties. It turns out that an equivalent way to accomplish an outcome variable ordering with respect to group differences is to examine ' F -to-remove' values via the use of the SPSS DISCRIMINANT program (see **Software for Statistical Analyses**). For Data Set B, the F -to-remove values are given in Table 2 – these are the F -transformations of Wilks lambda values obtained in the 15 14-variable analyses.

A second way to order the 15 outcome variables is to examine the absolute values of the two sets of 15 *structure r*'s. Such an ordering would reflect the relative contributions of the variables to the definitions of the respective resulting constructs. From Table 1 – trusting that all other *structure r*'s are 'low' – the relative importance of the five variables used to name the first construct is

Table 1 Selected *structure r*'s for Data Set B

	LDF_1	LDF_2
MINFO	0.68	
SINFO	0.50	
LINFO	0.46

IMPLS	0.61	14.5
SOCBL	0.09	14.5

obvious; similarly for the second construct. One could sum the squares of the two structure r 's for each of the 15 outcome variables and order the 15 variables with respect to the 15. Such an ordering would indicate the 'collective relative importance' to the definition of the pair of constructs. This latter ordering is rather generic and is judged to be of less interpretive value than the two separate orderings.

As illustrated above with Data Set B, what was discussed were the testing, construct identification, and variable ordering for the *omnibus* effects. That is, what are the effects of the grouping variable on the collection of 15 outcome variables? In some research, more specific questions are of interest. That is, there may be interest in group *contrast* effects (*see Analysis of Variance*). With Data Set B, for example, one might want to compare group 4 with any one of the other three groups or with the other three groups combined. With any contrast analysis – accomplished very simply with any computer package MANOVA program – there is only one LDF, which would be examined as above, assuming it is judged that the tested contrast effect is 'real.'

It is important to note that DDA methods are also applicable in the context of a **factorial design**, say, A-by-B. One may examine the LDF(s) for the **interaction effects**, for simple A effects, for simple B effects, or (if the interaction effects are not 'real') for main A effects and main B effects (*see Analysis of Variance*). Here, too, there may be some interest in contrast effects.

Whether a one-factor or a multiple-factor design is employed, the initial choice of the outcome variable set for a DDA is *very* important. Unless the variable set is, in some way, a substantive collection of analysis unit attributes, little, if any, meaningful interpretation can be made of the DDA results. If one has just a hodgepodge of p outcome variables, then what is suggested is that p univariate analyses be conducted – see [4].

Finally, with respect to DDA, there may be research situations in which multiple MANOVAs, along with multiple DDAs, may be conducted. Such a situation may exist when the collection of outcome variables constitutes multiple 'systems' of variables. Of course, each system would be comprised of a respectable number of outcome variables so that at least one construct might be meaningfully identified. (Should this have been considered with Data Set B?)

Group Membership Prediction

Suppose an educational researcher is interested in predicting student post-high-school experience using (a hodgepodge of) nine predictor variables. Let there be four criterion groups determined four years after ninth grade enrollment: college, vocational school, full-time job, and other. The nine predictor variable scores would be obtained prior to, or during, the ninth grade: four specific academic achievements, three family characteristics, and two survey-based attitudes. The analysis to be used with this $k = 4$, $p = 9$ design is PDA. The basic research question is: How well can the four post-high-school experiences be predicted using the nine predictors?

Another PDA example is that based on Data Set A in [1, p. 227]. The grouping variable is level of college French course – beginning ($n_1 = 35$), intermediate ($n_2 = 81$), and advanced ($n_3 = 37$). The $N = 153$ students were assessed on the following 13 variables prior to college entry:

- Five high school cumulative grade-point averages:
 - English (EGPA),
 - Mathematics (MGPA),
 - Social Science (SGPA),
 - Natural Science (NGPA),
 - French (FGPA);
- The number of semesters of high school French (SHSF);
- Four measures of academic aptitude
 - ACT English (ACTE),
 - ACT Mathematics (ACTM),
 - ACT Social Studies (ACTS),
 - ACT Natural Sciences (ACTN);
- Two scores on a French test:
 - ETS Aural Comprehension (ETSA),
 - ETS Grammar (ETSG); and
- The number of semesters since the last high school French course (SLHF).

It is assumed that French course enrollment was initially 'appropriate' – that is, the grouping variable is well defined. The purpose of the study, then, is to determine how well membership in $k = 3$ levels of college French can be predicted using scores on the $p = 13$ predictors. (Note that in PDA, the response variables are predictor variables, whereas in DDA the response variables are outcome variables. Also, in PDA, the grouping variable is an outcome

variable, whereas in DDA the grouping variable is a predictor variable.)

Assuming approximate multivariate normality (*see Multivariate Normality Tests*) of predictor variable scores in the k populations (see [1, Chs. IV & X]), there are two types of PDAs, linear and quadratic. A *linear prediction/classification rule* is appropriately used when the k group **covariance matrices** are in ‘the same ballpark.’ If so, a linear composite of the p predictors is determined for *each* of the k groups. (These linear composites are not the same as the LDFs determined in a DDA – different in number and different in derivation.) The linear combination/composite for each group is of the same general form as that in (1). For Data Set A, the first *linear classification function* (LCF) is

$$99.33 + 0.61 X_1 - 4.47 X_2 + 12.73 X_3 \\ + \cdots + 2.15 X_{13}. \quad (4)$$

The three sets of LCF weights, for this data set, are mathematically derived so as to maximize correct group classification for the data on hand. If it is to be concluded that the three population covariance matrices are not equal (see [6]), then a *quadratic prediction/classification rule* would be used. With this PDA, three quadratic classification functions (QCFs) involving the 13 predictors are derived (with the same mathematical criterion as for the linear prediction rule). The QCFs are rather complicated and lengthy, including weights for X_j , for X_j^2 and for $X_j X_{j'}$.

Whether one uses a linear rule or a quadratic rule in a group-membership prediction/classification study, there are two bases for group assignment. One basis is the *linear/quadratic composite score* for each analysis unit for each group – for each unit, there are k composite scores. A unit, then, is assigned to that group with which the larger(est) composite score is associated. The second basis is, for each unit, an estimated probability of group membership, given the unit’s vector of predictor scores; such a probability is called a *posterior probability* (*see Bayesian Statistics*). A unit, then, is assigned to that group with which the larger (or largest) posterior probability is associated. (For each unit, the sum of these probability estimates is 1.00.) The two bases will yield identical classification results.

Prior to discussing the summary of the group-membership prediction/classification results, there is another probability estimate that is *very* important

in the LCFs/QCFs and posterior probability calculations. This is a *prior* (or, *a priori*) *probability* (*see Bayesian Statistics*). The k priors reflect the relative sizes of the k populations and must sum to 1.00. The priors are included in both the composite scores and the posterior probabilities, and, thus, have an impact on group assignment. The values of the priors to be used may be based on theory, on established knowledge, or on expert judgment. The priors used for Data Set A are, respectively, 0.25, 0.50, and 0.25. (This implies that the proportion of students who enroll in, for example, the intermediate-level course is approximately 0.50.)

The calculation of LCF/QCF scores, for the data set on hand, are based on predictor weights that are determined from the very same data set (Similarly, calculation of the posterior probability estimates is based on mathematical expressions derived from the data set on hand.) In other words, the prediction rule is derived from the very data on which the rule is applied. Therefore, these group-membership prediction/classification results are (internally) biased – such a rule is considered an *internal rule*. Using an internal rule is NOT to be recommended in a PDA. Rather, an *external rule* should be employed. The external rule that I suggest is the *leave-one-out* (L-O-O) rule. The method used with the L-O-O approach involves N repetitions of the following two steps.

1. Delete one unit and derive the rule of choice (linear or quadratic) on the remaining $N-1$ units; and
2. Apply the rule of choice to the deleted unit.

(Note: At the time of this writing, the quadratic external (i.e., L-O-O) results yielded by SPSS are NOT correct. Both linear and quadratic external results are correctly yielded by the SAS package, while the SPSS package only yields correct *linear* external results.)

A basic summary of the prediction/classification results is in the form of a *classification table*. For Data Set A, the L-O-O linear classification results are given in Table 3. For this data set, the *separate-group hit rates* are $29/35 \doteq 0.83$ for group 1, $68/81 \doteq 0.84$ for Group 2, and $30/37 \doteq 0.81$ for group 3. The *total-group hit rate* is $(29 + 68 + 30)/153 \doteq 0.83$. (All four of these hit rates are inordinately ‘high.’) It is advisable, in my opinion, to assess the hit rates relative to chance. That is: Is an observed hit rate better than a hit rate that can be obtained by chance?

6 Discriminant Analysis

Table 3 Classification table for Data Set A

		Predicted group			
		1	2	3	
Actual group	1	29	6	0	35
	2	8	68	5	81
	3	0	7	30	37
		37	81	35	153

To address this question, one can use a *better-than-chance* index:

$$I = \frac{H_o - H_e}{H_e}, \quad (5)$$

where H_o is the observed hit rate, and H_e is the hit rate expected by chance. For the total-group hit rate using Data Set A, $H_o \doteq 0.83$ and $H_e \doteq (0.25 \times 35 + 0.50 \times 81 + .25 \times 37)/153 \doteq 0.38$; therefore, $I \doteq 0.72$. Thus, by using a linear external rule, about 72% fewer classification errors across all three groups would be made than if classification was done by chance. For group 3 alone, $I \doteq (0.81 - 0.25)/(1 - 0.25) \doteq 0.75$.

A researcher may want to ask two more specific PDA questions:

1. May some predictor(s) be deleted?
2. What are the more important predictors (with respect to some specific group hit rate, or to the total-group hit rate)?

The first question is a very important one – for practical purposes. (My experience has been that in virtually every PDA, at least one predictor may be discarded to result in a *better* prediction rule.) There are two reasonable analysis approaches for this question. One is the *p all-but-one-predictor analyses*. By examining the results, the predictor, when deleted, dropped the hit rate(s) of interest the least – or, which is more usual, increased the hit rate(s) of interest – could be deleted. After that is done, the $p - 1$ all-but-one-predictor analyses could be conducted. When to stop this process is a researcher judgment call. The second approach is to determine a ‘best’ subset of predictors for the hit rate(s) of interest. This may be done using an *all-subsets analysis*; that is, all subsets of size 1, of size 2, ..., of size $p - 1$. (J. D. Morris at Florida Atlantic University has written a computer program to conduct the all-subset L-O-O analyses.) Again, as

usual, judgment calls will have to be made about the retention of the final subset. For Data Set A, the best subset of the 13 predictors is comprised of six predictors (EGPA, MGPA, SGPA, NGPA, ETSA, and ETSG) with a total-group L-O-O hit rate (using the priors of 0.25, 0.50, and 0.25) of 0.88 (as compared to the total-group hit rate of 0.83 based on all 13 predictors).

The second question pertains to predictor ordering/relative importance. This may be simply addressed by conducting the *p* all-but-one-predictor analyses. The predictor, when deleted, that leads to the largest drop in the hit rates of interest, may be considered the most important one, and so on. For the $p = 13$ analyses with Data Set A, it is found that when variable 12 is deleted, the total-group hit drops the most, from 0.83 (with all 13 variables) to 0.73. Therefore, variable 12 is considered most important (with respect to the total-group hit rate). There are four variables, which when singly deleted, actually *increase* the total-group hit rate.

There are some other specific PDA-related aspects in which a researcher might have some interest. Such interest may arise when the developed prediction rule (in the form of a set of k linear or quadratic composites) is to be used with another, comparable sample. Four such aspects are listed here but will not be discussed: **outliers**, in-doubt units, nonnormal rules, and posterior probability threshold (see [1] for details).

Summary

The term ‘discriminant analysis’ may be viewed in two different ways. One, it is an analysis used to describe differences between/among groups of analysis units on the basis of scores on a ‘system’ of outcome variables. In a factorial-design context, this view would pertain to analyzing the interaction effects, main effects, and simple effects. This is when DDA is applicable. The second view is an analysis used to predict group membership on the basis of scores on a collection of predictor variables. This is when PDA is applicable. DDA and PDA are *different* analyses with *different* purposes, *different* computations, *different* interpretations, and *different* reporting [1, 5]. (With regard to the latter, I have witnessed many, many problems – see [3].) From my perspective, another view of DDA versus

PDA pertains to research context. DDA is applicable to ‘theoretical’ research questions, while PDA is applicable to ‘applied’ research questions. This relationship reminds me of an analogy involving multiple correlation and **multiple linear regression** (see [2]).

Distribution-free Inference, an Overview

Introduction

Nearly fifty years have passed since the 1956 publication of social psychologist Sidney Siegel's *Nonparametric Statistics for the Behavioral Sciences* [23] provided convenient access to a range of nonparametric or distribution-free procedures for researchers in psychology and other disciplines. The first edition of his book still actively circulates in no fewer than eight branches of my university's library, including the specialized collections in architecture, business administration, and marine biology. What was Siegel's motivation? What techniques did he provide the researchers of the 1950s? How has the nonparametric landscape evolved in recent years?

Importance of Level of Measurement

Siegel was motivated primarily by the mismatch between parametric statistics and the level of measurement (*see Scales of Measurement*) associated with many psychological scales. The *t* Test (*see Catalogue of Parametric Tests*) and the *analysis of variance* require scales that are not only numeric but at the interval or ratio level. Here are some representative exceptions:

- Potential car buyers report that they intend to purchase one of the following: a SUV, a minivan, a sedan, or a sports car. The four possible responses are nonnumeric and have no natural order. They form a set of nominal categories.
- Students rate their instructors on a five-point scale, ranging from poor through fair, good, and very good to excellent. The five possibilities form an ordinal scale of instructor performance. We could replace the verbal labels with numbers, but how big is the difference between fair and good compared with the difference between very good and excellent?
- The difference in intelligence between two 12-year old children with WISC IQ scores of 85 and 95 may or may not correspond to the difference in intelligence between another pair of twelve-year

olds with IQ scores of 135 and 145. Although the WISC scores are numeric, a researcher may want to treat the scores as providing a ranking or numeric ordering of the intelligences of tested children rather than as measuring those intelligences on an interval or, were zero IQ to be well-defined, a ratio scale.

The centrality to distribution-free statistics of scales of measurement is reinforced in a more recent standard text, the 1999 revision of Conover's *Practical Nonparametric Statistics* [4]. Conover offers this definition of nonparametric: 'A statistical method is nonparametric if it satisfies at least one of these criteria:

1. The method may be used on data with a nominal scale of measurement.
2. The method may be used on data with an ordinal scale of measurement.
3. The method may be used on data with an interval or ratio scale of measurement, where the distribution function is either unspecified or specified except for an infinite number of parameters.'

The last criterion includes, among others, instances in which (a) the normality of a distribution is in question, (b) that distribution is contaminated by **outliers**, or (c) observations are not identically distributed but are drawn from multiple parameterized distributions, perhaps as many distributions as there are observations.

Basic Distribution-free Techniques

Both [4] and [23] employ a 'factorial design' in presenting what I will call the 'basic' nonparametric techniques, crossing levels of measurement with a common set of research designs. Notably, the fly leaves of the two texts feature the resulting two-way table. I have utilized this structure in Table 1 to provide an overview of the basic distribution-free techniques and to show the extent of overlap between the 1956 and 1999 coverages. It should be noted that each of the two texts does mention techniques other than the ones listed here. Table 1 is limited to those statistics elevated to inclusion in the fly leaf table by one or other of the two authors.

In an important sense, the heart of classical distribution-free statistics is contained in footnote c

2 Distribution-free Inference, an Overview

^dActually classified as Ordinal in [23].

^eActually classified as Ordinal in [4].

to Table 1. Measures that are numeric, apparently on an interval scale, can be treated as ordinal data. We simply replace the numeric scores with their ranks. I will describe, however, the whole of Table 1 column by column.

In the first column of the table, data are categorical and the *Chi-squared Test*, introduced in a first statistics course, plays an important role (see **Contingency Tables**). In one-sample designs, it provides for testing a set of observed frequencies against a set of theoretical expectations (e.g., the proportions of blood types A, B, AB, and O) and in two-sample designs it provides for testing the equivalence of two distributions of a common set of categories. An accurate probability of incorrectly rejecting the null hypothesis is assured only asymptotically and is compromised where parameters are estimated in the first case.

The *Fisher Exact Test* (see **Exact Methods for Categorical Data**) provides, as its name implies, an exact test of the independence of row and column classifications in a 2×2 table of frequencies (see **Two by Two Contingency Tables**). Typically, the rows correspond to two treatments and the columns to two outcomes of treatment, so the test of independence is a test of the equality of the proportion of successes in the two treatment populations. Under the null hypothesis, the cell frequencies are regulated by a hypergeometric distribution (see **Catalogue of Probability Density Functions**) and that distribution allows the computation of an exact *P* value for either directional or nondirectional alternatives to independence. The chi-squared test is used frequently in this situation but yields only approximate probabilities and does not provide for directionality in the alternative hypothesis.

The **Binomial Test** invokes the family of binomial distributions (see **Catalogue of Probability Density Functions**) to test a hypothesis about the proportion of ‘successes’ in a distribution of successes and failures. One difference between [4] and [23] is that the former emphasizes hypothesis tests while the later reflects the more recent interest in the estimation of **confidence intervals** (CIs) for parameters such as the proportion of successes or, in the two-sample case, the difference in the proportions of success (see **Confidence Intervals: Nonparametric**).

The **Maentel–Haenszel Test** extends Fisher’s exact test to studies in which the two treatments have been evaluated, independently, in two or more populations. The null hypothesis is that the two treatments are equally successful in all populations. The alternative may be directional (e.g., that treatment ‘A’ will be superior to treatment ‘B’ in at least some populations and equivalent in the others) or nondirectional. *Cochran’s Q* is useful as an omnibus test of treatments in **randomized complete block designs** where the response to treatment is either a success or failure. As *Q* is a transformation of the usual Pearson chi-squared statistic, the suggested method for finding a *P* value is to refer the statistic to a chi-squared distribution. As noted earlier, the result is only approximately correct. Subsequent pairwise comparisons can be made with *McNemar’s Test for Significance of Change* (see **Matching**). The latter procedure can be used as well in matched pair designs for two treatments with dichotomous outcomes. Although significance for McNemar’s test usually is approximated by reference to a chi-squared distribution, Fisher’s exact test could be used to good effect.

The *Phi Coefficient* (see **Effect Size Measures**) expresses the association between two dichotomous classifications of a set of cases on a scale not unlike the usual correlation coefficient. As it is based on a 2×2 table of frequencies, significance can be assessed via Fisher’s exact test or approximated by reference to a chi-squared distribution. The several contingency coefficients that have been proposed transform the chi-squared statistic for a two-way table to a scale ranging from 0 for independence to some positive constant, sometimes 1, for perfect dependence. The underlying chi-squared statistic provides a basis for approximating a test of significance of the null hypothesis of independence.

The second column of Table 1 lists techniques requiring observations that can be ordered from smallest to largest, allowing for ties. The one sample **Runs Test** in [23] evaluates the randomness of a sequence of occurrences of two equally likely events (such as, heads and tails in the flips of a coin). The examples in [23] are based on numeric data, but as these are grouped into two events, the test could as well have appeared in the Nominal column. Exact *P* values are provided by the appropriate Binomial random variable with $p = 0.5$. Runs tests are deprecated in [4] as having less power than alternative tests.

The **Kolmogorov–Smirnov test** compares two cumulative distribution functions. The one-sample version compares an empirical distribution function with a theoretical one. The two-sample version compares two empirical distribution functions. The **Cramer–von Mises Test** is a variation on the two-sample Kolmogorov–Smirnov, again comparing two empirical cumulative distribution functions. *P* values for both two-sample tests can be obtained by permuting observations between the two sources.

The *Quantile Test* uses the properties of a Binomial distribution to test hypotheses about (or find CIs for) **quantiles**, such as the median or the 75th percentile, of a distribution. The Cox–Stuart Test groups a sequence of scores into pairs and then applies the **Sign Test** to the signs (positive or negative) of the pairwise differences to detect a trend in the data. The Sign Test itself is noted in [23] as the oldest of all distribution-free tests. The null hypothesis is that the two signs, + and –, have equal probability of occurring and the binomial random variable with $p = 0.5$ is used to test for significance. The *Daniels Test for Trend* is an alternative to the Cox–Stuart test. It uses **Spearman’s rho**, computed between the ranks of a set of observations and the order in which those observations were collected to assess trend. Below I mention how rho can be tested for significance.

The **Wilcoxon–Mann–Whitney Test** (WMW, it has two origins) has become the distribution-free rival to the *t* Test for comparing the magnitudes of scores in two-sampled distributions. The observations in the two samples are pooled and then ranked from smallest to largest. The test statistic is the sum of ranks for one of the samples and significance is evaluated by comparing this rank sum with those computed from all possible permutations of the ranks

between treatments. The rank sums can be used as well to find a CI for the difference in medians [4].

The two-sample **Median Test** evaluates the same hypothesis as the WMW by applying Fisher's exact test to the fourfold table created by noting the number of observations in each sample that are larger than or are smaller than the median for the combined samples. The *Wald–Wolfowitz Runs Test* approaches the question of whether the two samples were drawn from identical distributions by ordering the combined samples, smallest to largest, and counting the number of runs of the two sources in the resulting sequence. A Binomial random variable provides the reference distribution for testing significance.

The *Moses Test of Extreme Reactions* is tailored to a particular alternative hypothesis, that the 'active' treatment will produce extreme reactions, responses that are either very negative (small) or very positive (large). The combined samples are ranked as for the runs test and the test statistic is the span in ranks of the 'control' sample. Exact significance can be assessed by referring this span to the distribution of spans computed over all possible permutations of the ranks between the active and control treatments.

Just as the WMW test is the principal distribution-free alternative to the t Test, **Friedman's Test** is the nonparametric choice as an omnibus treatment test in the complete randomized block design (see **Randomized Block Design: Nonparametric Analyses**). Responses to treatment are ranked within each block and these ranks summed over blocks, separately for each treatment. The test statistic is the variance of these sums of treatment ranks. Exact significance is evaluated by comparing this variance with the distribution of variances resulting from all possible combinations of permutations of the ranks within blocks.

Friedman's test is an omnibus one. Where the alternative hypothesis specifies the order of effectiveness of the treatments, the *Page Test* can be used. The test statistic is the Spearman rank correlation between this order and the rank of treatment sums computed as for Friedman's test. Exact significance is assessed by comparing this correlation with those resulting, again, from all possible combinations of permutations of the ranks within blocks (see **Page's Ordered Alternatives Test**).

The k -sample *Median Test* tests the null hypothesis that the k -samples are drawn from populations

with a common median. The test statistic is the Pearson chi-squared statistic computed from the $2 \times k$ table of frequencies that results from counting the number of observations in each of the samples that are either smaller than or greater than the median of the combined samples. Approximate P values are provided by referring the statistic to the appropriate chi-squared distribution.

The **Kruskal–Wallis Test** is an extension of the WMW test to k independent samples. All observations are pooled and a rank assigned to each. These ranks are then summed separately for each sample. The test statistic is the variance of these rank sums. Exact significance is assessed by comparing this variance against a reference distribution made up of similar variances computed from all possible permutations of the ranks among the treatments.

The Kruskal–Wallis test is an omnibus test for equivalence of k treatments. By contrast, the **Jonckheere–Terpstra Test** has as its alternative hypothesis an ordering of expected treatment effectiveness. The test statistic can be evaluated for significance exactly by referring it to a distribution of similar values computed over all possible permutations of the ranks of the observations among treatments. In practice, the test statistic is computed on the basis of the raw observations, but as the computation is sensitive only to the ordering of these observations, ranks could be used to the same result.

Two distribution-free measures of association between a pair of measured attributes, **Spearman's Rho** and **Kendall's Tau**, are well known in the psychological literature. The first is simply the product–moment correlation computed between the two sets of ranks. Tau, however, is based on an assessment of the concordance or not of each of the $[n \times (n - 1)]/2$ pairs of bivariate observations. Though computed from the raw observations, the same value of τ would result if ranks were used instead. Significance of either can be assessed by comparing the statistic against those associated with all possible permutations of the Y scores (or their ranks) paired with the X scores (or their ranks).

To assess the degree of agreement among b raters, when assessing (or, ordering) k stimulus objects, **Kendall's Coefficient of Concordance** has been employed. Although W has a different computation, it is a monotonic function of the statistic used in Friedman's test for balanced designs with b blocks

and k treatments and can be similarly evaluated for significance.

The final column of Table 1 lists techniques that, arguably, require observations on an interval scale of measurement. There is some disagreement on the correct placement among [4, 23], and myself. I'll deal first, and quite briefly, with six techniques that quite clearly require interval measurement.

The *Lilliefors* and *Shapiro–Wilks* procedures are used primarily as tests of normality. Given a set of measurements on an interval scale, should we reject the hypothesis that it is a sample from a normal random variable? The *Squared Ranks* and *Klotz* tests are distribution-free tests of the equivalence of variances in two-sampled distributions. Variance implies measurement on an interval scale. While the **Slope Test** and CI Estimate employ Spearman's Rho and Kendall's Tau, the existence of a regression slope implies interval measurement. Similarly, *Monotonic Regression* uses ranks to estimate a regression curve, again defined only for interval measurement. The regression curve, whether linear or not, tracks the dependence of the mean of Y on the value of X . Means require interval measurement.

Usually, **Wilcoxon's Signed Ranks Test** is presented as an improvement on the Sign test, an Ordinal procedure. While the latter takes only the signs of a set of differences into account, Wilcoxon's procedure attaches those signs to the ranks of the absolute values of the differences. Under the null hypothesis, the difference in the sums of positive and negative ranks ought to be close to zero. An exact test is based on tabulating these sums for all of the 2^n possible assignments of signs to the ranks. Although only ranks are used in the statistic, our ability to rank differences, either differences between paired observations or differences between observations and a hypothesized median, depends upon an interval scale for the original observations. Wilcoxon's procedure can be used to estimate CIs for the median or median difference.

The *Walsh Test* is similar in purpose to the Signed Rank test but uses signed differences, actually pairwise averages of signed differences, rather than signed ranks of differences. It is a small sample procedure; [23] tables significant values only for sample sizes no larger than 15. The complete set of $[n \times (n - 1)]/2$ pairwise averages, known as **Walsh Averages** can be used to estimate the median

or median difference and to find a CI for that parameter.

The *Quade Test* extends Friedman's test by differentially weighting the contribution of each of the blocks. The weights are given by the ranks of the ranges of the raw observations in the block. the use of the range places this test in the Interval, rather than Ordinal column, of my Table 1. Quade's test statistic does not have a tractable exact distribution, so an approximation is used based on the parametric family of F random variables. It appears problematic whether this test does improve on Friedman's approach, which can be used as well with ordinal measures.

Both [4] and [23] list the *Permutation Test* (see **Permutation Based Inference**) as a distribution-free procedure for interval observations, though not under that name. It is referred to as the Randomization Test by [23] and as Fisher's Method of Randomization by [4]. I refer to it as the permutation test or, more explicitly, as the Raw Score Permutation Test and reserve the name Randomization Test for a related, but distinct, inferential technique. Incidentally, the listing of the permutation test in the Interval column of Table 1 for two independent samples has, perhaps, more to do with the hypothesis most often associated with the test than with the logic of the test. The null hypothesis is that the two samples are drawn from identical populations. Testing hypotheses about population means implies interval measurement. Testing hypotheses about population medians, on the other hand, may require only ordinal measurement.

We have already encountered important distribution-free procedures, including the Wilcoxon–Mann–Whitney and Kruskal–Wallis tests, for which significance can be assessed exactly by systematically permuting the ranks of observations among treatments. These tests can be thought of as Rank Permutation Tests. Raw score permutation test P values are obtained via the same route; we refer a test statistic computed from raw scores to a reference distribution made up of values of that statistic computed for all possible permutations of the raw scores among treatments.

I have identified a third class of permutation tests in the Interval column of Table 1 as *Normal Scores* tests (see **Normal Scores and Expected Order Statistics**). Briefly, these are permutation tests that are carried out after the raw scores have been replaced, not by their ranks, but by scores that

inherit their magnitudes from the standard Normal random variable while preserving the order of the observations. The ‘gaps’ between these normal scores will vary, unlike the constant unit difference between adjacent ranks. There are several ways of finding such normal scores. The Normal Scores Permutation Test is referred to as the *van der Waerden Test* by [4]. This name derives from the use as normal scores of quantiles of the Standard Normal random variable (mean of zero, variance of one). In particular, the k th of n ranked scores is transformed to the $q(k) = [k/(n + 1)]$ quantile of the Standard Normal, for example, for $k = 3, n = 10, q(k) = 3/11$. The corresponding van der Waerden score is that z score below which fall 3/11 of the distribution of the standard normal, that is, $z = -0.60$.

Normal scores tests have appealing power properties [4] although this can be offset somewhat by a loss in accuracy if normal theory approximations, rather than actual permutation reference distributions, are employed for hypothesis testing.

Had [23] and, for that matter, [4] solely described a set of distribution-free tests, the impact would have been minimal. What made the techniques valuable to researchers was the provision of tables of significant values for the tests. There are no fewer than 21 tables in [23] and 22 in [4]. These tables enable exact inference for smaller samples and facilitate the use of normal theory approximations for larger studies.

In addition to [4], other very good recent guides to these techniques include [13, 14, 19] and [25].

Growth of Distribution-free Inference

The growth of distribution-free inference beyond the techniques already surveyed has been considerable. Most of this growth has been facilitated, if not stimulated, by the almost universal availability of inexpensive, fast computing. These are some highlights.

The analysis of frequencies, tabulated by two or more sets of nominal categories, now extends far beyond the chi-squared test of independence thanks to the development [3] and subsequent popularization [2] of **Log Linear Models**. The flavor of these analyses is not unlike that of the analysis of factorial designs for measured data; what higher order interactions are needed to account for the data?

A graphical descriptive technique for cross-classified frequencies, as yet more popular with

French than with English or US researchers, is **Correspondence Analysis** [12, 15]. In its simplest form, the correspondence referred to is that between row and column categories. In effect, correspondence analysis decomposes the chi-squared lack of fit of a model to the observed frequencies into a number of, often interpretable, components.

Regression models for binary responses, known as **Logistic Regression**, pioneered by [5] now see wide usage [2]. As with linear regression, the regressors may be a mix of measured and categorical variables. Unlike linear regression, the estimation of model parameters must be carried out iteratively, as also is true for the fitting of many log linear models. Thus, the adoption of these techniques has required additional computational support. Though originally developed for two-level responses, logistic regression has been extended to cover multicategory responses, either nominal or ordinal [1, 2].

Researchers today have access to measures of association for cross-classified frequencies, such as the *Goodman–Kruskal Gamma* and *Tau* coefficients [11], that are much more informative than contingency coefficients.

Earlier, I noted that both [4] and [23] include (raw score) Permutation Tests among their distribution-free techniques. Though they predate most other distribution-free tests [22], their need for considerable computational support retarded their wide acceptance. Now that sufficient computing power is available, there is an awakening of interest in permutation inference, [10, 18] and [24], and the range of hypotheses that can be tested is expanding [20, 21].

Important to the use of permutation tests has been the realization that it is not necessary to survey all of the possible permutations of scores among treatments. Even with modern computing power, it remains a challenge to enumerate all the possible permutations when, for example, there are 16 observations in each of two samples: $[32!/(16! \times 16!)] = 601,080,390$. A Monte Carlo test (*see Monte Carlo Goodness of Fit Tests; Monte Carlo Simulation*) based on a reference distribution made up of the observed test statistic plus those resulting from an additional $(R - 1)$ randomly chosen permutations also provides an exact significance test [8, 18]. The power of this test increases with R , but with modern desktop computing power, an R of 10 000 or even larger is a quite realistic choice.

In his seminal series of papers, Pitman [22] noted that permutation tests were valid even where the samples ‘exhausted’ the population sampled. Though the terminology may seem odd, the situation described is both common and very critical. Consider the following.

A psychologist advertises, among undergraduates, for volunteers to participate in a study of visual perception. The researcher determines that 48 of the volunteers are qualified for the study and randomly divides those students into two treatment groups, a Low Illumination Level group and a High Illumination Level group. Notably, the 48 students are not a random sample from any larger population; they are a set of available cases. However, the two randomly formed treatment groups are random samples from that set and, of course, together they ‘exhaust’ that set. This is the situation to which Pitman referred. The set of available cases constitutes what I call a local population.

Parametric inference, for example, a t Test, assumes the 48 students to be randomly chosen from an essentially infinitely large population and is clearly inappropriate in this setting [8, 16, 17]. The permutation test mechanics, however, provide a valid test for the local population and Edgington [8] advocates, as do I, the use of the term *Randomization Test* when used in this situation (see **Randomization Based Tests**). The distinctive term serves to emphasize that the inference (a) is driven by the randomization rather than by random sampling and (b) that inference is limited to the local population rather than some infinitely large one.

Truly random samples remain a rarity in the behavioral sciences. Randomization, however, is a well-established experimental precaution and randomization tests ought to be more widely used than they have been [8, 16, 17]. In the preface to [4], the author notes that, in 1999, distribution-free methods are ‘essential tools’ for researchers doing statistical analyses. The authors of [14] go even further, declaring distribution-free tests to be the ‘preferred methodology’ for data analysts. There is some evidence, however, that psychologists may be reluctant to give up parametric techniques; in 1994, de Leuw [7] noted that there remained ‘analysis of variance oriented programs in psychology departments’.

Arguably, applications of the **Bootstrap** have had the greatest recent impact on distribution-free inference. The bootstrap provides a basis for estimating

standard errors and confidence intervals and for carrying out hypothesis tests on the basis of samples drawn by resampling from an initial random sample. The approach is computer intensive but has wide applications [6, 9, 17, 18, 24].

Fast computing has changed the statistical landscape forever. Parametric methods thrived, in large part, because their mathematics led to easy, albeit approximate and inaccurate, computations. That crutch is no longer needed.

Dominance

Dominance refers to the nonlinear interaction between alleles *within* a locus. In the case of a discrete trait, when the effect of one allele masks the effect of the other allele at a single locus, we say that the first allele exhibits dominance over the second allele. In the case of a quantitative trait, dominance is best illustrated in reference to the standard biometrical model. Consider a single autosomal biallelic locus (Figure 1). Let the genotypic value of the homozygote A_1A_1 be $+a$ and the genotypic value of the homozygote A_2A_2 be $-a$. The genotypic value of the heterozygote A_1A_2 depends upon the degree of dominance at the locus and is quantified by the parameter d . When there is no dominance ($d = 0$), then alleles A_1 and A_2 are said to act additively in that the genotypic value of the heterozygote is exactly half the sum of the genotypic values of the two homozygotes. When $d > 0$, allele A_1 displays dominance over allele A_2 . Conversely, when $d < 0$, allele A_2 displays dominance over allele A_1 . When dominance is complete, d is equal to $+a$ or $-a$ [3–5]. Note that the concept of dominance rests critically on the choice of scale used to measure the trait of interest, in that a trait may exhibit dominance when measured on one scale, but not when the trait is measured on a different transformed (e.g., logarithmic) scale [2, 9].

If one regresses the number of copies of an allele (say A_1) against genotypic value, it is possible to partition the genotypic value into an expected value based on additivity at the locus, and a deviation based on dominance. The proportion of variance in the genotypic value explained by the regression is the additive genetic variance (*see Additive Genetic Variance*). The residual variation, which is not explained by the regression, is referred to as

the *dominance genetic variance* and arises because of the nonlinear interaction between alleles at the same locus.

In the case of the biallelic locus above, the dominance (σ_D^2) variance is given by the formula:

$$\sigma_D^2 = (2pqd)^2 \quad (1)$$

Thus, the dominance variance is a function of both the allele frequencies in the population and the dominance parameter d . Note that a low proportion of dominance variance does not necessarily imply the absence of dominant gene action, but rather may be a consequence of the particular allele frequencies in the population [9].

The classical **twin design** which compares the similarity between monozygotic and dizygotic twins reared together may be used to estimate the amount of dominance variance contributing to a trait, although the power to do so is quite low [1, 8]. However, it is important to realize that it is not possible to estimate dominant genetic and shared environmental components of variance simultaneously using this design. This is because both these variance components are negatively confounded in a study of twins reared together. That is not to say that these components cannot contribute simultaneously to the trait variance, but rather they cannot be estimated from data on twins alone [6, 8]. When the correlation between monozygotic twins is greater than half the correlation between dizygotic twins, it is assumed that shared environmental factors do not influence the trait, and a dominance genetic component is estimated. In contrast, when the correlation between monozygotic twins is less than half the correlation between dizygotic twins, it is assumed that dominance genetic factors do not influence the trait and a shared environmental variance component is estimated. The consequence of this confounding is

Genotype	A_2A_2		A_1A_2	A_1A_1
Genotypic value	$-a$	0	d	$+a$
Genotypic frequency	q^2		$2pq$	p^2

Figure 1 A biallelic autosomal locus in Hardy–Weinberg equilibrium. The genotypic values of the homozygotes A_1A_1 and A_2A_2 are $+a$ and $-a$ respectively. The genotypic value of the heterozygote A_1A_2 is d , which quantifies the degree of dominance at the locus. The gene frequencies of alleles A_1 and A_2 are p and q respectively, and the frequencies of the genotypes are as shown

2 Dominance

that variance component estimates will be biased when dominance genetic and shared environmental components simultaneously contribute to trait variation [6–8].

Dot Chart

Many data sets consist of measurements on some continuous variable of interest recorded within the categories of a particular categorical variable. A very simple example would be height measurements for a sample of men and a sample of women. The dot chart, in which the position of a dot along a horizontal line indicates the value of the continuous measurement made within each of the categories involved, is often a useful graphic for making comparisons and identifying possible ‘outlying’ categories. An example of a dot chart is shown in Figure 1. The plot represents standardized mortality rates for lung cancer in 25 occupational groups; to enhance the usefulness of the graphic, the categories are ordered according to their mortality rates.

A dot chart is generally far more effective in communicating the pattern in the data than a **pie chart** or a **bar chart**.

Dropouts in Longitudinal Data

In longitudinal studies, research units (e.g., households, individual persons, establishments) are measured repeatedly over time (*see* **Longitudinal Data Analysis; Repeated Measures Analysis of Variance**). Usually, a limited number of separate measurement occasions or waves is used. The minimum number of waves is two, as in the classical pretest–posttest designs, that are well-known in intervention studies and experiments (*see* **Clinical Trials and Intervention Studies**). But, longitudinal studies can have any number of measurement occasions (waves) in time. If the number of occasions is very large this is called a **time series**. In a time series, a small number of research units is followed through time and measured on many different occasions on a few variables only. Examples of time series can be found in psychological studies, educational research, econometrics, and medicine. In social research and official statistics, a common form of longitudinal study is the panel survey. In a panel, a well-defined set of participants is surveyed repeatedly. In contrast to time series, panel surveys use a large number of research units and a large number of variables, while the number of time points is limited. Examples are budget surveys, election studies, socioeconomic panels, and general household panels (*see* **Panel Study**). In the following sections, most examples will come from panel surveys and survey methodology. However, the principles discussed also apply to other types of longitudinal studies and other disciplines.

The validity of *any* longitudinal study can be threatened by dropout (*see* **Dropouts in Longitudinal Studies: Methods of Analysis**). If the dropout is *selective*, if the missing data are not missing randomly, than the results may be biased. For instance, if in a panel of elderly, the oldest members and those in ill-health drop out more often, or if in a clinical trial for premature infants, the lightest infants are more likely to stay in the intervention group, while the more healthy, heavier babies drop out over time. When one knows who the dropouts are and why the dropout occurs, one can statistically adjust for dropout (*see* **Dropouts in Longitudinal Studies: Methods of Analysis; Missing Data**). But this is far

from simple, and the more one knows about the missing data, the better one can adjust. So, the first step in good adjustment is to prevent dropout as much as possible, and collect as much data as possible of people who may eventually drop out. But even if the dropout is not selective, even if people are missing completely at random, this may still cause problems in the analysis. The smaller number of cases will result in less statistical power and increased variance. Furthermore, in subgroup comparisons, dropout may lead to a very small number of persons in a particular subgroup. Again the best strategy is to limit the problem by avoiding dropout as far as possible.

Nonresponse in longitudinal studies can occur at different points in time. First of all, not everyone who is invited to participate in a longitudinal study will do so. This is called *initial nonresponse*. Especially when the response burden is heavy, initial nonresponse at recruitment may be high. Initial nonresponse threatens the representativeness of the entire longitudinal study. Therefore, at the beginning of each longitudinal study one should first of all try to reduce the initial nonresponse as much as possible, and secondly collect as much data as possible on the nonrespondents to be used in statistical adjustment (e.g., weighting). Initial nonresponse is beyond the scope of this entry, but has been a topic of great interest for survey methodologist (*see* **Nonresponse in Sample Surveys**), and in the past decade much empirical knowledge on nonrespondents and reduction of nonresponse has been collected [1].

After the initial recruitment, when research participants have agreed to cooperate in the longitudinal study, nonresponse can occur at every time point or wave. This is called *dropout*. Dropout or wave nonresponse occurs when a participant in the study does not produce a completed questionnaire or interview at a specific time point, or fails to appear at a scheduled appointment in an experiment. If after a certain time point, research participants stop responding to all subsequent questionnaires or interviews, this is called *attrition* or *panel mortality*.

Finally, besides dropout, there is another source of nonresponse that may threaten the validity of longitudinal data and should be taken into account: item nonresponse. When item nonresponse occurs a unit (e.g., research participant, respondent) provides data, but for some reason data on particular questions or measurements are not available for analysis. Item

2 Dropouts in Longitudinal Data

nonresponse is beyond the scope of this entry; for an introductory overview on prevention and treatment of item nonresponse, see [2].

Starting at the initial recruitment, the researcher has to take steps to reduce future nonresponse. This needs careful planning and a total design approach. As research participants will be contacted over time, it is extremely important that the study has a well-defined image and is easily recognized and remembered at the next wave. A salient title, a recognizable logo, and graphical design are strong tools to create a positive study identity, and should be consistently used on all survey materials. For instance, the same logo and graphical style can be used on questionnaires, interviewer identity cards, information material, newsletters, and thank-you cards. When incentives are used, one should try to tie these in with the study. A good example comes from a large German study on exposure to printed media. The logo and mascot of this study is a little duckling, Paula. In German, the word 'Ente' or duck has the same meaning as the French word 'canard': a false (newspaper) report. Duckling Paula appears on postcards for the panel members, as a soft toy for the children, as an ornament for the Christmas tree, printed on aprons, t-shirts and so on, and has become a collector's item.

Dropout in longitudinal studies originates from three sources: failure to locate the research unit, failure to contact the potential respondent, and failure to obtain cooperation from the response unit [3].

Thus, the first task is limiting problems in *locating* research participants. At the recruitment phase or during the base-line study, the sample is fresh and address information is up-to-date. As time goes by, people move, and address, phone, and e-mail information may no longer be valid. It is of the utmost importance, that from the start at each consecutive time point, special locating information is collected. Besides the full name, also the maiden name should be recorded to facilitate follow-up after divorce. It is advisable to collect full addresses and phone numbers of at least three good friends or relatives as 'network contacts.' Depending on the study, names and addresses of parents, school-administration, or employers may be asked too. One should always provide 'change-of-address-cards' and if the budget allows, print on this card a message conveying that if one sends in a change of address, the researchers

will send a small 'welcome in your new home-gift' (e.g., a flower token, a DIY-shop token, a monetary incentive). It goes without saying, that the change-of-address cards are preaddressed to the study administration and that no postage is needed.

When the waves or follow-up times are close together, there is opportunity to keep locating-information up-to-date. If this is not the case, for instance in an annual or biannual study, it pays to incorporate between-wave locating efforts. For instance, sending a Christmas card with a spare 'change-of-address card', birthday cards for panel-members, and sending a newsletter with a request for address update. Additional strategies are to keep in touch and follow-up at known life events (e.g., pregnancy, illness, completion of education). This is not only motivating for respondents; it also limits loss of contact as change-of-address cards can be attached. Any mailing that is returned as undeliverable should be tracked immediately. Again, the better the contact ties in with the goal and topic of the study, the better it works. Examples are mother's day cards in a longitudinal study of infants, and individual feedback and growth curves in health studies. A total design approach should be adopted with material identifiable by house style, mascot, and logo, so that it is clear that the mail (e.g., child's birthday card) is coming from the study. Also ask regularly for an update, or additional network addresses. This is extremely important for groups that are mobile, such as young adults.

If the data are collected by means of face-to-face or telephone interviews, the interviewers should be clearly instructed in procedures for locating respondents, both during training and in a special tracking manual. Difficult cases may be allocated to specialized 'trackers'. Maintaining interviewer and tracker morale, through training, feedback, and bonuses helps to attain a high response. If other data collection procedures are used (e.g., mail or internet survey, experimental, or clinical measurements), staff members should be trained in tracking procedures. Trackers have to be trained in use of resources (e.g., phone books, telephone information services), and in the approach of listed contacts. These contacts are often the only means to successfully locate the research participant, and establishing rapport and maintaining the conversation with contacts are essential.

The second task is limiting the problems in *contacting* research participants. The first contact in a longitudinal study takes effort to achieve, just like establishing contact in a cross-sectional, one-time survey. Interviewers have to make numerous calls at different times, leave cards after a visit, leave messages on answering machines, or contact neighbors to extract information on the best time to reach the intended household. However, after the initial recruitment or base-line wave, contacting research participants is far less of a problem. Information collected at the initial contact can be fed to interviewers and used to tailor later contact attempts, provided, of course, that good locating-information is also available. In health studies and experimental research, participants often have to travel to a special site, such as a hospital, a mobile van, or an office. Contacts to schedule appointments should preferably be made by phone, using trained staff. If contact is being made through the mail, a phone number should always be available to allow research participants to change an inconvenient appointment, and trained staff members should immediately follow-up on 'no-shows'.

The third task is limiting dropout through lost willingness to cooperate. There is an extensive literature on increasing the cooperation in cross-sectional surveys. Central in this is reducing the cost for the respondent, while increasing the reward, motivating respondents and interviewers, and personalizing and tailoring the approach to the respondent [1, 4, 5]. These principles can be applied both during recruitment and at subsequent time points. When interviewers are used, it is crucial that interviewers are kept motivated and feel valued and committed. This can be done through refresher training, informal interviewer meetings, and interviewer incentives. Interviewers can and should be trained in special techniques to persuade and motivate respondents, and learn to develop a good relationship [1]. It is not strictly necessary to have the same interviewers revisit the same respondents at all time points, but it is necessary to feed interviewers information about previous contacts. Also, personalizing and adapting the wording of the questions by incorporating answers from previous measurements (dependent interviewing) has a positive effect on cooperation.

In general, prior experiences and especially 'respondent enjoyment' is related to cooperation at

subsequent waves [3]. A short and well-designed questionnaire helps to reduce response burden. Researchers should realize this and not try to get as much as possible out of the research participants at the first waves. In general, make the experience as nice as possible and provide positive feedback at each contact.

Many survey design features that limit *locating* problems, such as sending birthday and holiday cards and newsletters, also serve to nurture a good relationship with respondents and keep them motivated. In addition to these intrinsic incentives, explicit incentives also work well in retaining cooperation, and do not appear to have a negative effect on data quality [1]. Again the better the incentives fit the respondent and the survey, the better the motivational power (e.g., free downloadable software in a student-internet panel, air miles in travel studies, cute t-shirt and toys in infant studies). When research participants have to travel to a special site, a strong incentive is a special transportation service, such as a shuttle bus or car. Of course, all real transportation costs of participants should be reimbursed. In general, everything that can be done to make participation in a study as easy and comfortable as possible should be done. For example, provide for child-care during an on-site health study of teenage mothers.

Finally, a failure to cooperate at a specific time point does not necessarily imply a complete dropout from the study. A respondent may drop out temporarily because of time pressure or lifetime changes (e.g., change of job, birth of child, death of spouse). If a special attempt is made, the respondent may not be lost for the next waves.

In addition to the general measures described above, each longitudinal study can and should use data from earlier time points to design for nonresponse prevention. Analysis of nonrespondents (persons unable to locate again and refusals) provides profiles for groups at risk. Extra effort then may be put into research participants with similar profiles who are still in the study (e.g., offer an extra incentive, try to get additional network information). In addition, these nonresponse analyses provide data for better statistical adjustment.

With special techniques, it is possible to reduce dropout in longitudinal studies considerably, but it can never be prevented completely. Therefore, adjustment procedures will be necessary during analysis.

4 Dropouts in Longitudinal Data

Knowing why dropout occurs makes it possible to choose the correct statistical adjustment procedure. Research participants may drop out of longitudinal studies for various reasons, but of one thing one may be assured: they do not drop out completely at random. If the reasons for dropout are not related to the topic of the study, responses are missing at random and relatively simple weighting or imputation procedures can be adequately employed. But if the reasons for dropout *are* related to the topic, responses are *not* missing at random and a special model for the dropout must be included in the analysis to prevent bias. In longitudinal studies, usually auxiliary data are available from earlier time points, but one can only guess at the reasons why people drop out. It is advisable to ask for these reasons directly in a special short exit-interview. The data from this exit interview, together with auxiliary data collected at earlier time points, can then be used to statistically model the dropout and avoid biased results.

Dropouts in Longitudinal Studies: Methods of Analysis

Introduction

In longitudinal behavioral studies, it is difficult to obtain outcome measures for all participants throughout the study. When study entry is staggered, participants entering late may not have a complete set of measures at the time of analysis. Some participants may move and lose contact with the study, and others may drop out for reasons related to the study outcomes; for example, in a study of pain, individuals who do not obtain relief may discontinue treatments, or in a study of treatments to stop smoking, people who continue to smoke may be more likely to drop out of the study rather than admit to lack of success. These mechanisms of drop out create problems for the analysis, since the cases that remain are a biased sample and may distort treatment comparisons, particularly if the degree of dropout is differential between treatment arms.

In the **clinical trial** setting, a useful distinction [11] is between *treatment* dropouts, where individuals discontinue an assigned treatment, and *analysis* dropouts, where outcome data are not recorded. A treatment dropout is not necessarily an analysis dropout, in that study outcomes can still be recorded after the lapse in treatment protocol. Since these outcomes do not reflect the full effect of the treatment, the values that would have been recorded if the participant had remained in the study might still be regarded as missing, converting a treatment dropout into an analysis dropout. For discussion of treatment dropouts and, more generally, *treatment compliance*, see [2]. From now on, I focus the discussion on methods for handling analysis dropouts.

In general, any method for handling dropouts requires assumptions, and cannot fully compensate for the loss of information. Hence, the methods discussed here should not substitute for good *study design* to minimize dropout, for example, by keeping track of participants and encouraging them to continue in the study. If participants drop out, efforts should be made to obtain some information (for

example, the reason for drop out) since that can be useful for statistical analysis.

Complete-case Analysis and Imputation

A simple way of dealing with **missing data** is complete-case (CC) analysis, also known as listwise deletion, where incomplete cases are discarded and standard analysis methods are applied to the complete cases (e.g., [10, Chapter 3]). In many statistical packages, this is the default analysis. The exclusion of incomplete cases represents a loss of information, but a more serious problem is that the complete cases are often a biased sample. A useful way of assessing this is to compare the observed characteristics of completers and dropouts, for example, with *t* Tests, comparing means or chi-squared tests, comparing categorical variables. A lack of significant differences indicates that there is no evidence of bias, but this is far from conclusive since the groups may still differ on the outcomes of interest.

A simple approach to incomplete data that retains the information in the incomplete cases is to impute or fill in the missing values (e.g., [10, Chapter 4], and see **Multiple Imputation**). It is helpful to think of imputations as being based on an imputation model that leads to a predictive distribution of the missing values. Missing values are then either imputed using the mean of this predictive distribution, or as a random draw from the predictive distribution. Imputing means leads to consistent estimates of means and totals from the filled-in data; imputing draws is less efficient, but has the advantage that nonlinear quantities, such as variances and percentiles, are also consistently estimated from the imputed data.

Examples of predictive mean imputation methods include unconditional mean imputation, where the sample mean of the observed cases is imputed, and regression imputation, where each missing value is replaced by a prediction from a regression on observed variables (see **Multiple Linear Regression**). In the case of univariate nonresponse, with $Y_1, \dots, Y_{k-1}$ fully observed and Y_k sometimes missing, the regression of Y_k on $Y_1, \dots, Y_{k-1}$ is estimated from the complete cases, including interactions, and the resulting prediction equation is used to impute the estimated conditional mean for each missing value of Y_k . Regression imputation is superior to unconditional mean imputation since it exploits and preserves

relationships between imputed and observed variables that are otherwise distorted. For repeated-measures data with dropouts, missing values can be filled in sequentially, with each missing value for each subject imputed by regression on the observed or previously imputed values for that subject.

Imputation methods that impute draws include *stochastic regression* imputation [10, Example 4.5], where each missing value is replaced by its regression prediction plus a random error with variance equal to the estimated residual variance. A common approach for longitudinal data imputes missing values for a case with the last recorded observation for that case. This method is common, but not recommended since it makes the very strong and often unjustified assumption that the missing values in a case are all identical to the last observed value. Better methods for longitudinal imputation include imputation based on row and column fits [10, Example 4.11].

The imputation methods discussed so far can yield consistent estimates of the parameters under well-specified imputation models, but the analysis of the filled-in data set does not take into account the added uncertainty from the imputations. Thus, statistical inferences are distorted, in the sense that standard errors of parameter estimates computed from the filled-in data will typically be too small, **confidence intervals** will not have their nominal coverage, and *P* values will be too small. An important refinement of imputation, **multiple imputation**, addresses this problem [18]. A predictive distribution of plausible values is generated for each missing value using a statistical model or some other procedure. We then impute, not just one, but a set of *M* (say *M* = 10) draws from the predictive distribution of the missing values, yielding *M* data-sets with different draws plugged in for each of the missing values. For example, the stochastic regression method described above could be repeated *M* times. We then apply the analysis to each of the *M* data-sets and combine the results in a simple way. In particular, for a single parameter, the multiple-imputation estimate is the average of the estimates from the *M* data-sets, and the variance of the estimate is the average of the variances from the *M* data-sets plus $1 + 1/5$ times the sample variance of the estimates over the *M* data-sets (The factor $1 + 1/M$ is a small-*M* correction). The last quantity here estimates the contribution to the variance from imputation uncertainty, missed by single imputation methods. Similar formulae apply

for more than one parameter, with variances replaced by covariance matrices. For other forms of multiple-imputation inference, see [10, 18, 20]. Often, multiple imputation is not much more difficult than doing single imputation; most of the work is in creating good predictive distributions for the missing values. Software for multiple imputation is becoming more accessible, see PROC MI in [15], [19], [20] and [22].

Maximum Likelihood Methods

Complete-case analysis and imputation achieve a rectangular data set by deleting the incomplete cases or filling in the gaps in the data set. There are other methods of analysis that do not require a rectangular data set, and, hence, can include all the data without deletion or imputation. One such approach is to define a summary measure of the treatment effect for each individual based on the available data, such as change in an outcome between baseline and last recorded measurement, and then carry out an analysis of the summary measure across individuals (*see Summary Measure Analysis of Longitudinal Data*). For example, treatments might be compared in terms of differences in means of this summary measure. Since the precision of the estimated summary measure varies according to the number of measurements, a proper statistical analysis gives less weight to measures from subjects with shorter intervals of measurement. The appropriate choice of weight depends on the relative size of intraindividual and interindividual variation, leading to complexities that negate the simplicity of the approach [9].

Methods based on **generalized estimating equations** [7, 12, 17] also do not require rectangular data. The most common form of estimating equation is to generate a likelihood function for the observed data based on a statistical model, and then estimate the parameters to maximize this likelihood [10, chapter 6]. **Maximum likelihood** methods for multilevel or **linear multilevel models** form the basis of a number of recent statistical software packages for repeated-measures data with missing values, which provide very flexible tools for statistical modeling of data with dropouts. Examples include SAS PROC MIXED and PROC NL MIXED [19], methods for longitudinal data in S-PLUS functions *lme* and *nlme* [13], HLM [16], and the Stata programs

gllamm in [14] (see **Software for Statistical Analyses**). Many of these programs are based on linear multilevel models for normal responses [6], but some allow for binary and ordinal outcomes [5, 14, 19] (see **Generalized Linear Mixed Models**).

These maximum likelihood analyses are based on the *ignorable* likelihood, which does not include a term for the missing data mechanism. The key assumption is that the data are *missing at random*, which means that dropout depends only on the observed variables for that case, and not on the missing values or the unobserved random effects (see [10], chapter 6). In other words, missingness is allowed to depend on values of covariates, or on values of repeated measures recorded prior to drop out, but cannot depend on other quantities. Bayesian methods (see **Bayesian Statistics**) [3] under noninformative priors are useful for small sample inferences.

Some new methods allow us to deal with situations where the data are not missing at random, by modeling the joint distribution of the data and the missing data mechanism, formulated by including a variable that indicates the pattern of missing data [Chapter 15 in 10], [1, 4, 8, 14, 23, 24]. However, these nonignorable models are very hard to specify and vulnerable to model misspecification. Rather than attempting simultaneously to estimate the parameters of the dropout mechanism and the parameters of the complete-data model, a more reliable approach is to do a **sensitivity analysis** to see how much the answers change for various assumptions about the dropout mechanism (see [Examples 15.10 and 15.12 in 10], [21]). For example, in a smoking cessation trial, a common practice is to treat dropouts as treatment failures. An analysis based on this assumption might be compared with an analysis that treats the dropouts as missing at random. If substantive results are similar, the analysis provides some degree of confidence in the robustness of the conclusions.

Conclusion

Complete-case analysis is a limited approach, but it might suffice with small amounts of dropout. Otherwise, two powerful general approaches to statistical analysis are maximum likelihood estimation and multiple imputation. When the imputation model and the

analysis model are the same, these methods have similar large-sample properties. One useful feature of multiple imputation is that the imputation model can differ from the analysis model, as when variables not included in the final analysis model are included in the imputation model [10, Section 10.2.4]. Software for both approaches is gradually improving in terms of the range of models accommodated. Deviations from the assumption of missing at random are best handled by a sensitivity analysis, where results are assessed under a variety of plausible alternatives.

Dummy Variables

A categorical variable with more than two levels is, in effect, a collection of $k - 1$ variables where k is the number of levels of the categorical variable in question. Consider the categorical variable Religious Denomination. For the sake of simplicity, let us say that it contains three levels: Christian, Muslim, and Jewish. If we were to code these three levels 1, 2, and 3, we might have a data set as in Table 1:

We could use this variable as a predictor of Political Conservatism (PC). Thus, we could regress a measure of PC onto our Religion variable. The regression weight for the Religion variable would be gibberish, however, because the predictor was coded arbitrarily. A regression weight gives the expected change in the dependent variable per single point increase in the predictor. When a predictor is arbitrarily coded, a single point increase has no meaning. The numbers in the RelDen column are merely labels, and they could have been assigned to the groups in any combination. Thus, the regression weight would be very different if we had chosen a different arbitrary coding scheme.

The problem stems from the fact that this categorical variable actually contains $k - 1 = 2$ comparisons among the k groups. In order to capture all of the information contained in the distinctions among these groups, we must have all $k - 1 = 2$ of these comparisons. The generic term for such a comparison variable is *Dummy Variable*.

Strictly speaking, a dummy variable is a dichotomous variable such that if a given subject belongs to a particular group, that subject is given a score of 1 on the dummy variable. Members of other groups are given a zero. One way of handling the Religion

Table 1 Data for a 3-level categorical variable

Subject #	RelDen
1	1
2	2
3	3
4	1
5	2
6	3

Table 2 Data and dummy codes for a 3-level categorical variable

Subject #	RelDen	Dummy1	Dummy2
1	1	1	0
2	2	0	1
3	3	0	0
4	1	1	0
5	2	0	1
6	3	0	0

variable above would be to create two dummy variables to represent its three levels. Thus, we would have data such as those in Table 2.

Dummy1 is coded such that Christians receive a 1 while Muslims and Jews receive a zero. Dummy2 is coded such that Muslims receive a 1 while Jews receive a zero. These two dummy variables as a set contain all of the information contained in the three-level Religion variable. That is, if I know someone's score on both of the dummy variables, then I know exactly which group that person belongs to: someone with a 1 and a 0 is a Christian, someone with a 0 and 1 is a Muslim, and someone with two zeros is a Jew. Because there is no variable for which Jews receive a 1, this is labeled the uncoded group.

Consider once again the prediction of PC from Religion. Whereas the three-level categorical variable cannot be used as a predictor, the two dummy variables can. Regression weights for dummy variables involve comparisons to the uncoded group. Thus, the weight for Dummy1 would be the difference between the PC mean for Christians and the PC mean for Jews (the uncoded group). The weight for Dummy2 would be the difference between the PC mean for Muslims and the PC mean for Jews. The R-squared from the regression of PC onto the set of dummy variables represents the percentage of PC variance accounted for by Religious Denomination.

The more general term for such coded variables is *Design Variable*, of which dummy coding is an example. Other examples are effect coding (in which the uncoded group is coded -1 instead of 0) and contrast coding (in which coded variables can take on any number of values). The appropriateness of a coding scheme depends on the sorts of comparisons that are of most interest.

Ecological Fallacy

Introduction to Ecological Fallacy

Ecological fallacy is an old term from the fifties, described for the first time by Robinson [4]. The fallacy is defined as the mistake a consumer of research results makes when a statistical effect (e.g., a correlation), measured and calculated over groups, is used as a statement valid for individuals. The opposite, a less common mistake in research, is the same fallacy. In the world outside research, this last fallacy would be called *discrimination*. Discrimination is blaming a group for the behavior of an individual, such as if someone who is Dutch, like myself, behaves badly, and the inference is made that all Dutch people behave that way. To avoid ecological fallacies, all data analysis results should be stated at the level where the analysis was executed. In sum, statements that make cross-level inferences should be avoided, unless good evidence exists that they are safe to make. A better solution is to analyze data at both levels of the hierarchy in multilevel analysis [1] and [3], which is a separate issue (*see Linear Multilevel Models*).

The Robinson Effect

Robinson [4] published the first example of an ecological fallacy, based on data collected in 1930. Reported correlations showed a strong relationship between the percentage immigrants and the level of illiteracy in the United States. The contradiction in the data, according to Robinson, was between the large and negative correlation ($r = -0.53$) using states as the unit of analysis, and the much smaller and positive correlation ($r = 0.12$) when individuals are the unit of analysis. The negative correlation indicates that if a state has a high percentage of foreign-born people, the level of illiteracy of that state is low, while the individual correlation indicates that foreign-born individuals are more often illiterate. This reversal of the correlation sign can be traced to an unmeasured third variable, affluence of a state, as shown by Hanushek, Jackson, and Kain [2]. In the thirties, affluent states attracted more immigrants, and, at the same time, affluence gave children more

opportunities to learn and go to school, thus lowering the illiteracy in the state as a whole.

Ecological Fallacy is Still Around

Kreft and De Leeuw [3] report an example of the relationship between education and income measured over people working in 12 different industries. The individual correlation is low but positive ($r = 0.12$). However, the aggregated correlation over industries is high and has a negative sign ($r = -0.71$). At individual level, a positive relation between education and income is found, but when the data are aggregated to industry level, the opposite appears to be true. The data suggest that individuals can expect some gain in income by going back to school, but, at the industry level, the reverse seems to be true. The opposite conclusion at the industry level is the result of a confounding factor, the type of industry, which is either private or public. In the private sector, high-paying industries exist that do not require high levels of education (e.g., transportation, real estate), while in the public sector, some low-paying industries are present, such as universities and schools, demanding high levels of schooling. Again, it is clear that characteristics of industries are a threat to the validity of cross-level inferences.

Conditions Where Ecological Fallacies May Appear

When interested in individual as well as group effects, the data matrix (and the covariance matrix) will be divided in two parts: a within (group) and a between (group) part, as shown in equation (1), where C = covariance, t = total, b = between, and w = within.

$$C(x_t, y_t) = C(x_b, y_b) + C(x_w, y_w) \quad (1)$$

The variances (V) of variables x and y can be defined in similar ways. A measure for between-group variance for a variable is defined as η^2 . η^2 is the ratio of between-group and total variation (*see Effect Size Measures*). Equally, the within-group variation is $1 - \eta^2$ the ratio of the within-group variation and the total variation. Ecological differences in regression coefficients occur when between and within variations are very different, and/or one of the two is (almost) zero. Given that

2 Ecological Fallacy

the total regression coefficient (b_t) is a weighted sum of the between-group regression b_b and the pooled-within group regression b_w , as in $b_t = \eta^2 b_b + (1 - \eta^2) b_w$, it follows that if $b_b = 0$, $b_t = b_w$, and the total regression are equal to the pooled-within regression. Following the same reasoning, $b_t = b_b$ when $b_w = 0$. In this situation, there is no pooled-within regression, and all the variation is between groups.

Using the definition of the regression coefficient for the total, the between as well as for the within group, as $\{C(xy)/V(x)\}$, it can be shown that the total regression coefficient is different from the within and/or the between-coefficient in predictable ways. The definition of the regression coefficient b_b in (2) is:

$$b(x_b, y_b) = \frac{C(x_b, y_b)}{V(x_b)} \quad (2)$$

Using the definition of η^2 and $1 - \eta^2$, we can replace the between-covariance, $C(x_b, y_b)$, in the numerator by the total covariance minus the within-covariance. The between-regression coefficient is redefined in (3):

$$b(x_b, y_b) = \frac{\{C(x_t, y_t) - C(x_w, y_w)\}}{V(x_b)} \quad (3)$$

Rearranging terms in (3), and replacing the total- as well as the within-covariances in the numerator by $b(x_t, y_t)V(x_t)$ and $b(x_w, y_w)V(x_w)$ respectively results in (4).

$$b(x_b, y_b) = \frac{\{b(x_t, y_t)V(x_t) - b(x_w, y_w)V(x_w)\}}{V(x_b)} \quad (4)$$

Dividing numerator and denominator in (4) by the total variance $V(x_t)$ and replacing the resulting $V(x_b)/V(x_t)$ by $\eta^2(x)$, doing the same with $V(x_w)/V(x_t)$ and replacing it with $1 - \eta^2(x)$ results in (5).

$$b(x_b, y_b) = \frac{\{b(x_t, y_t) - b(x_w, y_w)(1 - \eta^2(x))\}}{\eta^2(x)} \quad (5)$$

Equation (5) shows that the between-regression coefficient is the total regression coefficient minus the within-coefficient, weighted by the within- and between- η^2 . In situations where the regression coefficient between x and y is zero, $\{b(x_t, y_t) = 0\}$, the between-groups coefficients will be a weighted sum of the within-regression as in (6) and have an opposite sign.

$$b(x_b, y_b) = \frac{\{-b(x_w, y_w)(1 - \eta^2(x))\}}{\eta^2(x)} \quad (6)$$

The same equation (6) also shows that, if the group effect, $\eta^2(x)$, is large, $\{1 - \eta^2(x)\}$ will be small, both resulting in a larger between-coefficient than a within-coefficient, explaining the ‘blowing up’ of the aggregated coefficient as compared to the individual one.

Educational Psychology: Measuring Change Over Time

Educational psychologists examine many teaching and learning phenomena that involve change. For instance, researchers are interested in how students' abilities to read, spell, and write develop in elementary school. Investigators who study social and emotional variables such as personality traits and self-esteem examine how these variables change from adolescence to adulthood. Similarly, educators invested in the promotion of health and fitness are concerned with ways to improve eating, sleeping, and exercise behaviors. All of these examples lead to research questions for which investigators collect data to determine how variable scores change.

To address whether scores change in time, educational researchers often use **repeated measures analyses of variance (ANOVA)**. Studies employing repeated measures designs in educational psychological research are prevalent as any inspection of the best journals in the field shows [8, 17, 23]. Repeated measures ANOVA is simply an extension of the dependent samples t Test. Rather than comparing mean performance for the same group of examinees on two occasions (e.g., days, weeks, years – what statisticians refer to as trials), repeated measures ANOVA allows statisticians to compare means for three or more trials.

GLM for Repeated Measures and Statistical Assumptions

Repeated measures analyses are examined within the framework of the **Generalized Linear Model (GLM)** in statistics. Suppose an educational psychologist is interested in whether spelling scores for a group of elementary students change over a five-week period. Assume the researcher administers a spelling test every Friday of each week. According to Glass and Hopkins [7], any spelling score can be denoted by the symbol, X_{st} , where the subscripts s and t stand for s th student and t th trial, respectively. Thus, any score can be represented by the following equation:

$$X_{st} = \mu + a_s + \beta_t + a\beta_{st} + \varepsilon_{st}, \quad (1)$$

where μ is the grand mean, a_s is the random factor effect for students, β_t is the fixed factor effect for trials, $a\beta_{st}$ is an interaction term, and ε_{st} is the residual of the score X_{st} when predicted from the other terms in the model. Because of the inclusion of one random factor (students) and one fixed factor (trials), this repeated measures ANOVA model is a mixed-effects model (see **Linear Multilevel Models**).

As with all **analysis of variance (ANOVA)** models within the GLM framework, to determine whether there is a significant main effect for trial, the educational psychologist should report the F -ratio, degrees of freedom, the Mean Square Error term, and an index of effect size. Often, the partial eta-squared (η^2) value is reported to indicate small, medium, and large effects (0.01, 0.06, and 0.16 respectively) [3] (see **Effect Size Measures**).

Before investigators conclude, however, that at least one trial is different from the other four, they must ensure that certain statistical assumptions are met. Like other ANOVA models, the typical assumptions of normality and independence of observations are important in repeated measures analyses, too. In addition, statisticians must test the assumption of **sphericity** when analyzing repeated measures data. This assumption requires that the variances for all possible differences between trials be equal. The assumption relates to the dependency that exists between distributions of trials because the data come from the same students. Of course, researchers do not expect the variances of the differences to be exactly identical. Instead, they want to know if they differ to a significant degree.

Fortunately, there are many well-known tests of the sphericity assumption. Greenhouse and Geisser's [9] and Huynh and Feldt's [12] procedures adjust the degrees of freedom of the F test when the sphericity assumption is violated. To determine if it is violated, their procedures result in epsilon values (ε 's, which are reported in printouts such as those of SPSS [22]). Values close to 1.00 are desirable. If the Greenhouse–Geisser or Huynh–Feldt values suggest some departure from sphericity, it might be wise to adjust the degrees of freedom. Adjustment makes for a more *conservative* test, which means that a larger F -ratio is required to reject H_0 .

After researchers determine that there is a significant main effect for trials, two follow-up questions can be addressed: (a) Between which pairs of means is there significant change? (b) Is there

a significant trend across weeks? These two questions pertain to *post hoc* comparisons and trend analysis (see **Multiple Comparison Procedures**), respectively. Statistically, both topics are addressed extensively in the literature [15, 21]. However, with repeated measures designs, educational psychologists must be very careful about the interpretations they make. The next two sections describe some methodological considerations.

Post Hoc Comparisons

Readers can browse any textbook containing chapters on ANOVA, and find ample information about *post hoc* (see **A Priori v Post Hoc Testing**) comparisons. These mean comparisons are made after a so-called omnibus test is significant [13]. Thus, any time there is a main effect for a factor with more than two levels, *post hoc* comparisons indicate where the significant difference or differences are. *Post hoc* comparisons control familywise error rates (see **Error Rates**) (the probability of a Type I error is α for the set of comparisons). For between-subjects designs, educational psychologists can choose from many *post hoc* comparisons (e.g., Duncan, Fisher's least significant difference (LSD), Student–Newman–Kuels, Tukey's honestly significant difference (HSD)). For repeated measures analyses, do well-known *post hoc* comparison procedures work? Unfortunately, the answer is not a simple one, and statisticians vary in their opinions about the best way to approach the question [11, 16]. Reasons for the complexity pertain to the methodological considerations of analyzing repeated measures data. One concern about locating mean differences relates to violations of the assumption of sphericity. Quite often, the degrees of freedom must be adjusted for the omnibus F test because the assumption is violated. While statistical adjustments such as the Greenhouse–Geisser correction assist in accurately rejecting the null hypothesis for the main effect, *post hoc* comparisons are not protected by the same adjustment [18].

Fortunately, Keselman and his colleagues [13, 14] continue to study repeated measures designs extensively. In their papers, they recommend the best methods of comparing means given violations of sphericity or multiple sphericity (for designs with grouping variables). Reviewing these recommendations is beyond the scope of this chapter, but

Bonferroni methods appear particularly useful and result in fewer Type I errors than other tests (e.g., Tukey) when assumptions (such as sphericity) are violated [16].

Trend Analysis

While *post hoc* comparison procedures are one way to examine the means for repeated measures designs, another approach to studying average performance over time is trend analysis. Tests of linear and non-linear trends in studies of growth and development in educational psychology appear periodically [4]. Glass and Hopkins [7] indicate that as long as the repeated trials constitute an ordinal or interval scale of measurement, such as the case of weeks, tests for significant trends are appropriate. However, if the repeated factors are actually related measures, such as different subscale averages of a standardized test battery, then trend analyses are not appropriate. Thus, educational psychologists should not use trend analysis to study within-student differences on the graduate record examination (GRE) quantitative, verbal, and analytic subscales (see **Growth Curve Modeling**).

Figure 1 depicts a trend for hypothetical spelling data collected over a five-week period. Using standard contrasts, software programs such as SPSS [22] readily report whether the data fit linear, quadratic, cubic, or higher-order polynomial models. For the means reported in Table 1, the linear trend is significant, $F(1, 9) = 21.16$, $p = 0.001$, $MSe = 1.00$, partial $\eta^2 = 0.70$. The effect size, 0.70, is large. The data support the idea that students' spelling ability increases in a linear fashion.

Figure 1 Trend for spelling scores across weeks

Table 1 Means and standard deviations for hypothetical (SD) spelling data

Trial	Phonics instruction M (SD)	Control M (SD)	Total M (SD)
Week 1	1.60 (0.70)	1.20 (0.92)	1.40 (0.82)
Week 2	3.00 (1.15)	1.20 (0.79)	2.10 (1.33)
Week 3	4.90 (1.66)	2.00 (1.15)	3.45 (2.04)
Week 4	6.10 (2.08)	2.40 (1.17)	4.25 (2.51)
Week 5	7.70 (2.26)	2.90 (1.45)	5.30 (3.08)

Table 2 Analysis of Variance for instruction level (I) and Trials (T)

Source of variation	SS	df	MS	F
Between subjects	322.20	19		
Instruction (I)	184.96	1	184.96	24.27 ^a
Students (s : I)	137.24	18	7.62	
Within subjects	302.8	80		
Trials (T)	199.50	4	49.87	79.15*
I × T	57.74	4	14.44	22.92*
T × s : I	45.56	72	0.63	
Total	625	99		

^a $p < 0.0001$.

The Mixed-effects Model: Adding a Between-subjects Factor

To this point, the features of a repeated measures analysis of one factor (i.e., trials) have been presented. However, educational psychologists rarely test such simple models. Instead, they often study whether instructional interventions differ and whether the differences remain constant across time [5, 6]. Suppose an experimental variable is added to the repeated measures model for the hypothetical spelling data. Assume students are now randomly assigned to two conditions, a treatment condition that teaches students to spell using phonics-based instruction (Phonics) and a no instruction (Control) condition. Again, spelling scores are collected every Friday for five weeks. Means and standard deviations are reported in Table 1. Treatment (Phonics vs Control) is a between-subjects variable, Trials remains a within-subjects variable, and now there is an interaction between the two variables. In this analysis, students are nested in treatment condition. Table 2 presents the ANOVA source table for this model.

Three F-ratios are of interest. Researchers want to know if there is (a) a main effect for treatment; (b) a

main effect for trials; and, (c) an interaction between treatment and trials. In this analysis, the I (instruction mode) × T (trials) interaction is significant, $F(4, 72) = 22.92$, $p < 0.0001$, $MSe = 0.63$, partial $\eta^2 = 0.55$ (a large effect) as is the main effect for treatment, $F(1, 18) = 24.27$, $p < 0.0001$, $MSe = 7.62$, partial $\eta^2 = 0.55$, and trials, $F(4, 72) = 79.15$, $p < 0.0001$, $MSe = 0.63$, partial $\eta^2 = 0.55$. Statisticians recommend that researchers describe significant interactions before describing main effects because main effects for the first factor do not generalize over levels of the second factor (*see Interaction Effects*). Thus, even though the F-ratios are large for both main effects tests (i.e., treatment and trials), differences between treatment groups are not consistently the same for every weekly trial. Similarly, growth patterns across weekly trials are not similar for both treatment conditions.

Figure 2 illustrates the interaction visually. It displays two trend lines (Phonics and Control). Linear trends for both groups are significant. However, the slope for the Phonics Instruction group is steeper than that observed for the Control Group resulting in a significant I × T linear trend interaction, $F(1, 18) = 34.99$, $p < 0.0001$, $MSe = 1.64$, partial $\eta^2 = 0.56$. Descriptively, the results support the idea that increases in spelling ability over time are larger for the Phonics Instruction group than they are for the Control group. In fact, while hypothetical data are summarized here to show that Phonics Instruction has an effect on spelling performance when compared with a control condition, the results reflect those reported by researchers in educational psychology [24].

**Figure 2** Trends for spelling scores across weeks by treatment group

Assumption Considerations

The same statistical assumptions considered earlier apply to this mixed model. Thus, sphericity is still important. Because of the inclusion of two mutually exclusive groups, the assumption is called *multisample sphericity*. Not only must the variances of the differences of scores for all trial pairs be equal within a group but also the variances of the differences for all trial pairs must be consistent across groups. In the data analyzed, the assumption was not met. When analyzed by SPSS [22], adjustments of the degrees of freedom are recommended. For example, the uncorrected degrees of freedom for the interaction in Table 2 are 4 and 72, but the Greenhouse–Geisser degrees of freedom are 2.083 for the numerator and 37.488 for the denominator.

New Developments in Repeated Measures Analysis

The hypothetical spelling examples assume that students are randomly selected from the population of interest, and that they are randomly assigned to treatment conditions. The design in the second study was balanced as there were 10 students in each instruction level. Data were recorded for each student in a condition for every weekly trial. There were no missing data. Statistically, the design features of the examples are ideal.

Realistically, however, educational psychologists encounter design problems because data are not so ideal. Schools are not places where it is easy to randomly select students or randomly assign students to treatment conditions. Even if a special classroom or academic laboratory is available to the researcher, students interact, and converse regularly about their academic and social experiences. Further, instructors teach spelling independently of what they might learn from a Phonics Instruction intervention. From a statistical perspective, these data distributions likely violate the assumption of independence of observations.

To overcome this problem, researchers use several procedures. First, they can randomly select larger units of analysis such as classrooms, schools, or districts. Students, of course, would be nested in these larger units. Districts or schools would then be randomly assigned to treatment condition. Hierarchical Linear Modeling (HLM) [1], an extension of

the GLM, allows researchers to test multilevel models (see **Linear Multilevel Models**) where nested units of analysis are of interest to the researcher. Bryk and Raudenbush [1] show how these models can incorporate repeated measures factors and result in **growth curve modeling**. Thus, it is possible to analyze trends in Figures 1 and 2 with consideration of nested effects (e.g., how teachers in specific classrooms affect students' development, or how school districts affect achievement – independently of the effects of a treatment).

While HLM models help overcome violations of the assumption of independence, and, while they can incorporate repeated measures designs, they have limitations. Specifically, statistical **power** is an important consideration when selecting adequate sample sizes to test treatment effects. One must recall that these sample sizes now represent the highest level of the nested unit. As such, samples of districts, schools, or classrooms are selected rather than students who may be enrolled in one or two schools. Researchers, therefore, must consider the feasibility of their designs in terms of time and personnel needed to conduct investigations at this level.

Additionally, educational psychologists must consider the number of variables studied. In the hypothetical example, spelling is a simple construct representing one general kind of ability. Recent publications reveal constructs that are complex and multidimensional. Further, because the constructs are psychological traits, they are **latent variables** [2] rather than manifest variables such as hours, height, speed, and weight. Typically, latent variables are judged by how they predict scores on multiple-choice or rating scale items. Data reduction techniques like **exploratory factor analysis** (EFA) or **confirmatory factor analysis** (CFA) are then used to establish construct validity of scales. Educational psychologists then study the stability of these latent variables over time.

Guay, Marsh, and Boivin [10], for example, analyzed the relationships between academic self-concept and academic achievement of elementary students over time using a form of repeated measures testing **Structural Equation Models** (SEM) [19, 20]. These models allow researchers to inspect relationships between multiple dependent variables (either latent or manifest) as they are predicted from a set of independent variables. Further, the relationships between independent and dependent variables

can be examined in waves. That is, construct relationships can be examined for stability over time.

McDonald and Ho [20] provide a good resource of recommended practices in testing SEMs. Results in testing SEMs are best when (a) researchers outline a very good theory for how constructs are related and how they will change; (b) several exploratory studies guide the models' structure; and, (c) sample sizes are sufficient to ensure that the estimates of model parameters are stable.

A Summary of Statistical Techniques Used by Educational Psychologists

Unfortunately, educational psychologists have not relied extensively on HLM and SEM analyses with repeated measures of manifest or latent variables to test their hypotheses. A review of 116 studies in *Contemporary Educational Psychology* and *Journal of Educational Psychology* between 2001 and 2003 showed that 48 articles included tests of models with within-subjects factors. Of these, only four studies tested HLM models with repeated measures with at least two time periods. Of these four studies, only one incorporated growth curve modeling to examine differences in student performance over multiple time periods. As for SEM, eight studies tested multiple waves of repeated and/or related measures. Perhaps the lack of HLM and SEM models may be due to sample size limitations. HLM and SEM model parameters are estimated using **maximum likelihood** procedures. Maximum likelihood procedures require large sample sizes for estimation [10]. Alternatively, HLM and SEM research may not be prevalent, since the investigations of educational psychologists are often exploratory in nature. Thus, researchers may not be ready to confirm relationships or effects using HLM or SEM models [19, 20].

Certainly, the exploratory investigations could help the researchers replicate studies that eventually lead to test of HLM or SEM models where relationships or effects can be confirmed. Additionally, because educational psychologists are interested in individual differences, more studies should examine changes in latent and manifest variables at the student level for multiple time points [2]. **Time series analysis** is one statistical technique that educational psychologists can use to study developmental changes within individuals. Only 3 of the 168 studies reported use of time series analyses.

Table 3 Within-subjects methods in contemporary educational psychology research (2001–2003)

Technique	Frequency
Repeated-measures ANOVA	11
Related-measures ANOVA	11
Reporting effect sizes	9
SEM	8
Regression	5
MANOVA for repeated measures	4
Nonparametric repeated measures	4
HLM	4
Time series	3
Testing of assumptions	2

Note: Frequencies represent the number of articles that used a specific technique. Some articles reported more than one technique.

Table 3 lists the methods used in the 48 within-subjects design studies. As can be seen, only two studies addressed the assumptions of repeated measures designs (e.g., normality of distributions, independence of observations, sphericity). Only 9 of the 48 reported effect sizes. In a few instances, investigators used nonparametric procedures when their scales of measurement were nominal or ordinal, or when their data violated normality assumptions.

As long as researchers in educational psychology are interested in change and development, repeated measures analysis will continue to be needed to answer their empirical questions. Methodologists should ensure that important assumptions such as sphericity and independence of observations are met. Finally, there have been many recent developments in repeated measures techniques. HLM and SEM procedures can be used to study complex variables, their relationships, and how these relationships change in time. Additionally, time series analyses are recommended for examination of within-subject changes, especially for variables that theoretically should not remain stable over time (e.g., anxiety, situational interest, selective attention). As with all quantitative research, sound theory, quality measurement, adequate sampling, and careful consideration of experimental design factors help investigators contribute useful and lasting information to their field.

Effect Size Measures

Measures of effect magnitude help researchers determine if research results are important, valuable, or useful. A variety of statistics are used to measure effect magnitude. Many of the statistics fall into one of two categories: measures of effect size (typically, standardized mean differences) and measures of strength of association. In addition, there is a large group of statistics that do not fit into either category. A partial listing of effect magnitude statistics is given in Table 1.

The statistics play an important role in behavioral research. They are used to (a) estimate the sample size required to achieve an acceptable **power**, (b) integrate the results of empirical research studies in **meta-analyses**, (c) supplement the information provided by null-hypothesis significance tests, and (d) determine whether research results are practically significant [47]. Practical significance is concerned with the usefulness of results. Statistical significance, the focus of null-hypothesis significance tests, is concerned with whether results are due to chance or sampling variability.

Limitations of Null-hypothesis Significance Testing

To appreciate the role that measures of effect magnitude play in the research enterprise, it is necessary to understand the limitations of classical null-hypothesis significance testing. Null-hypothesis significance testing procedures, as practiced today, were developed between 1915 and 1933 by three men: **Ronald A. Fisher** (1890–1962), **Jerzy Neyman** (1894–1981), and **Egon S. Pearson** (1895–1980). Fisher was primarily responsible for the new paradigm and for advocating 0.05 as the standard significance level [51]. **Cohen** [13, p. 1307] observed that, ‘The fact that Fisher’s ideas quickly became the basis for statistical inference in the behavioral sciences is not surprising—they were very attractive. They offered a deterministic scheme, mechanical and objective, independent of content, and led to clear-cut yes-no decisions.’ In spite of these apparent advantages, the logic and usefulness of null-hypothesis significance testing has been debated for over 70 years. One of

the earliest negative critiques appeared in a 1938 article by Joseph Berkson [4]. Since then, the number of negative critiques has escalated [2, 7, 8, 13, 15, 23, 39, 55, 68, 71, 73]. One frequent criticism of null-hypothesis significance testing is that it answers the wrong question [3, 7, 15, 19, 22]. For example, in scientific inference, what researchers want to know is the probability that the null hypothesis (H_0) is true, given that they have obtained a set of data (D); that is, $p(H_0|D)$. What null-hypothesis significance testing tells them is the probability of obtaining these data or more extreme data if the null hypothesis is true, $p(D|H_0)$. Unfortunately for researchers, obtaining data for which $p(D|H_0)$ is low does not imply that $p(H_0|D)$ also is low. Falk [22] pointed out that $p(D|H_0)$ and $p(H_0|D)$ can be equal, but only under rare mathematical conditions.

Another criticism is that null-hypothesis significance testing is a trivial exercise because all null hypotheses are false. **John Tukey** [79, p. 100] expressed this idea as follows: ‘the effects of A and B are always different—in some decimal place—for any A and B. Thus asking “Are the effects different?” is foolish.’ More recently, Jones and Tukey [40, p. 412] reiterated this view.

For large, finite, treatment populations, a total census is at least conceivable, and we cannot imagine an outcome for which $\mu_A - \mu_B = 0$ when the dependent variable (or any other variable) is measured to an indefinitely large number of decimal places. . . . The population mean difference may be trivially small but will always be positive or negative.

The view that all null hypotheses are false, except those we construct, for Monte Carlo tests of statistical procedures is shared by many researchers [2, 4, 13, 34, 77]. Hence, because Type I errors cannot occur, statistically significant results are assured if large enough samples are used. Thompson [77, p. 799] captured the essence of this view when he wrote, ‘Statistical testing becomes a tautological search for enough participants to achieve statistical significance. If we fail to reject, it is only because we’ve been too lazy to drag in enough participants.’

A third criticism of null-hypothesis significance testing is that by adopting a fixed level of significance, a researcher turns a continuum of uncertainty into a dichotomous reject-do not reject decision [25, 30, 67, 81]. A null-hypothesis significance test provides a probability, called a *P* value, of observing a research result given that the null hypothesis is true.

2 Effect Size Measures

Table 1 Measures of effect magnitude

Measures of effect size	Measures of strength of association	Other measures
Cohen's [12] d, f, g, h, q, w	$r, r_{pb}, r_s, r^2, R, R^2, \eta, \eta^2, \eta_{mult}^2, \phi, \phi^2$	Absolute risk reduction (ARR)
Glass's [28] g'	Chambers' [9] r_e	Cliff's [10] p
Hedges's [36] g	Cohen's [12] f^2	Cohen's [12] U_1, U_2, U_3
Mahalanobis's D	Contingency coefficient (C)	Doksum's [20] shift function
Mean ₁ – Mean ₂	Cramér's [17] V	Dunlap's [21] common language effect size for bivariate correlation (CL _R)
Median ₁ – Median ₂	Fisher's [24] Z	Grisson's [31] probability of superiority (PS)
Mode ₁ – Mode ₂	Friedman's [26] r_m	Logit d'
Rosenthal and Rubin's [62] Π	Goodman & Kruskal's [29] λ, γ	McGraw & Wong's [54] common language effect size (CL)
Tang's [75] ϕ	Hays's [35] $\hat{\omega}^2, \hat{\omega}_{Y A,B,AB}^2, \hat{\rho}_1, \hat{\rho}_2$	Odds ratio ($\hat{\omega}$)
Thompson's [78] d^*	$\hat{\rho}_{Y A,B,AB}$	Preece's [59] ratio of success rates
Wilcox's [82] $\hat{\Lambda}_{Mdn, \sigma_b}$	Herzberg's [38] R^2	Probit d'
Wilcox & Muska's [84] $\hat{Q}_{0.632}$	Kelley's [42] ε^2	Relative risk (RR)
	Kendall's [43] W	Risk difference
	Lord's [53] R^2	Sánchez-Meca, Marín-Martínez, & Chacón-Moscó [69] d_{Cox}
	Olejnik & Algina [58] $\hat{\omega}_G^2, \hat{\eta}_G^2$	Rosenthal and Rubin's [61] binomial effect size display (BESD)
	Rosenthal and Rubin's [64] $r_{equivalent}^2$	Rosenthal & Rubin's [63] counternull value of an effect size ($ES_{counternull}$)
	Rosnow, Rosenthal, & Rubin's [66] $r_{alerting}, r_{contrast}, r_{effect\ size}$	Wilcox's [82] probability of superiority (λ)
	Tatsuoka's [76] $\hat{\omega}_{mult. c}^2$	
	Wherry's [80] R^2	

A P value only slightly larger than the level of significance is treated the same as a much larger P value. The adoption of 0.05 as the dividing point between significance and nonsignificance is quite arbitrary. The comment by Rosnow and Rosenthal [65] is pertinent, 'surely, God loves the 0.06 nearly as much as the 0.05'.

A fourth criticism of null-hypothesis significance testing is that it does not address the question of whether results are important, valuable, or useful, that is, their practical significance. The fifth edition of the *Publication Manual of the American Psychological Association* [1, pp. 25–26] explicitly recognizes this limitation of null-hypothesis significance tests.

Neither of the two types of probability value (significance level and P value) directly reflects the magnitude of an effect or the strength of a relationship. For the reader to fully understand the importance of your findings, it is almost always necessary to include some index of effect size or strength of relationship in your Results section.

Researchers want to answer three basic questions from their research [48]: (a) Is an observed effect real or should it be attributed to chance? (b) If the effect is real, how large is it? and (c) Is the effect

large enough to be useful; that is, is it practically significant? As noted earlier, null-hypothesis significance tests only address the first question. Descriptive statistics, measures of effect magnitude, and **Confidence Intervals** address the second question and provide a basis for answering the third question. Answering the third question, is the effect large enough to be useful or practically significant?, calls for a judgment. The judgment is influenced by a variety of considerations including the researcher's value system, societal concerns, assessment of costs and benefits, and so on. One point is evident, statistical significance and practical significance address different questions. Researchers should follow the advice of the *Publication Manual of the American Psychological Association* [1], 'provide the reader not only with information about statistical significance but also with enough information to assess the magnitude of the observed effect or relationship' (pp. 25–26). In the following sections, a variety of measures of effect magnitude are described that can help a researcher assess the practical significance of research results.

Effect Size

In 1969, Cohen introduced the first effect size measure that was explicitly labeled as such. His measure

is given by,

$$\delta = \frac{\psi}{\sigma} = \frac{\mu_E - \mu_C}{\sigma}, \quad (1)$$

where μ_E and μ_C denote the population means of the experimental and control groups and σ denotes the common population standard deviation [11]. Cohen recognized that the size of the contrast $\psi = \mu_E - \mu_C$ is influenced by the scale of measurement of the means. He divided the contrast by σ to rescale the contrast in units of the amount of error variability in the data. Rescaling is useful when the measurement units are arbitrary or have no inherent meaning. Rescaling also can be useful in performing power and sample size computations and in comparing effect sizes across research literatures involving diverse, idiosyncratic measurement scales. However, rescaling serves no purpose when a variable is always measured on a standard scale. Safety experts, for example, always measure contrasts of driver reaction times in seconds and pediatricians always measure contrasts of birth weights in pounds and ounces [5].

For nonstandard scales, Cohen's contribution is significant because he provided guidelines for interpreting the magnitude of δ . He said that $\delta = 0.2$ is a small effect, $\delta = 0.5$ is a medium effect, and $\delta = 0.8$ is a large effect. According to Cohen [14], a medium effect of 0.5 is visible to the naked eye of a careful observer. A small effect of 0.2 is noticeably smaller than medium, but not so small as to be trivial. Only an expert would be able to detect a small effect. A large effect of 0.8 is the same distance above medium as small is below it. A large effect would be obvious to anyone. From another perspective, a small effect is one for which 58% of participants in one group exceed the mean of participants in another group. A medium effect is one for which 69% of participants in one group exceed the mean of another group. And finally, a large effect is one for which 79% of participants exceed the mean of another group.

By assigning numbers to the labels small, medium, and large, Cohen provided researchers with guidelines for interpreting the size of treatment effects. His effect size measure is a valuable supplement to the information provided by a P value. A P value of 0.0001 loses its luster if the effect turns out to be trivial.

In most research settings, the parameters of Cohen's δ are unknown. In such cases, the sample means of the experimental and control groups are used to estimate μ_E and μ_C . An estimator of σ can

be obtained in a number of ways. Under the assumption that σ_E and σ_C are equal, the sample variances of the experimental and control groups are pooled as follows:

$$\hat{\sigma}_{\text{Pooled}} = \sqrt{\frac{(n_E - 1)\hat{\sigma}_E^2 + (n_C - 1)\hat{\sigma}_C^2}{(n_E - 1) + (n_C - 1)}}, \quad (2)$$

where n_E and n_C denote respectively the sample size of the experimental and control groups. An estimator of δ is

$$d = \frac{\bar{Y}_E - \bar{Y}_C}{\hat{\sigma}_{\text{Pooled}}}, \quad (3)$$

where $\bar{Y}_E$ and $\bar{Y}_C$ denote respectively the sample mean of the experimental and control groups, and $\hat{\sigma}_{\text{Pooled}}$ denotes the pooled estimator of σ . Gene Glass's [28] pioneering work on **meta-analysis** led him to recommend a different approach to estimating σ . He reasoned that if there were several experimental groups and a control group, pairwise pooling of the sample standard deviation of each experimental group with that of the control group could result in different values of $\hat{\sigma}_{\text{Pooled}}$ for the various contrasts. Hence, when the standard deviations of the experimental groups differed, the same size difference between experimental and control means would result in different effect sizes. Glass's solution was to use the sample standard deviation of the control group, $\hat{\sigma}_C$, to estimate σ . Glass's estimator of δ is

$$g' = \frac{\bar{Y}_{E_j} - \bar{Y}_C}{\hat{\sigma}_C}, \quad (4)$$

where $\bar{Y}_{E_j}$ and $\bar{Y}_C$ denote respectively the sample mean of the j th experimental group and the sample mean of the control group. Larry Hedges [36] recommended yet another approach to estimating σ . He observed that population variances are often homogeneous, in which case the most precise estimate of the population variance is obtained by pooling the $j = 1, \dots, p$ sample variances. His pooled estimator,

$$\hat{\sigma}_{\text{Pooled}} = \sqrt{\frac{(n_1 - 1)\hat{\sigma}_1^2 + \dots + (n_p - 1)\hat{\sigma}_p^2}{(n_1 - 1) + \dots + (n_p - 1)}}, \quad (5)$$

is identical to the square root of the within-groups mean square in a completely randomized analysis of variance. Hedges' estimator of δ is

$$g = \frac{\bar{Y}_{E_j} - \bar{Y}_C}{\hat{\sigma}_{\text{Pooled}}}. \quad (6)$$

4 Effect Size Measures

Hedges [36] observed that all three estimators of δ — d , g' , and g —are biased. He recommended correcting g for bias as follows,

$$g_c = J(N - 2)g, \quad (7)$$

where $J(N - 2)$ is the bias correction factor described in Hedges and Olkin [37]. The correction factor is approximately

$$J(N - 2) \cong \left(1 - \frac{3}{4N - 9}\right), \quad (8)$$

where $N = n_E + n_C$. Hedges [36] showed that g_c is the unique, uniformly minimum variance-unbiased estimator of δ . He also described an approximate confidence interval for δ :

$$g_c - z_{\alpha/2}\hat{\sigma}(g_c) \leq \delta \leq g_c + z_{\alpha/2}\hat{\sigma}(g_c),$$

where $z_{\alpha/2}$ denotes the two-tailed critical value that cuts off the upper $\alpha/2$ region of the standard normal distribution and

$$\hat{\sigma}(g_c) = \sqrt{\frac{n_E + n_C}{n_E n_C} + \frac{g_c^2}{2(n_E + n_C)}}. \quad (9)$$

Procedures for obtaining exact confidence intervals for δ using noncentral sampling distributions are described by Cumming and Finch [18].

Cohen's δ has been widely embraced by researchers because (a) it is easy to understand and interpret across different research studies, (b) the sampling distributions of estimators of δ are well understood, and (c) estimators of δ can be easily computed from t statistics and F statistics with one-degree-of-freedom that are reported in published articles. The latter feature is particularly attractive to researchers who do meta-analyses.

The correct way to conceptualize and compute the denominator of δ can be problematic when the treatment is a classification or organismic variable [27, 32, 57]. For experiments with a manipulated treatment and random assignment of the treatment levels to participants, the computation of an effect size such as g_c is relatively straightforward. The denominator of g_c is the square root of the within-groups mean square. This mean square provides an estimate of σ that reflects the variability of observations for the full range of the manipulated treatment. However, when the treatment is an organismic variable, such as gender, boys and girls, the square root of the

within-groups mean square may not reflect the variability for the full range of the treatment because it is a pooled measure of the variation of boys alone and the variation of girls alone. If there is a gender effect, the within-groups mean square reflects the variation for a partial range of the gender variable. The variation for the full range of the gender variable is given by the total mean square and will be larger than the within-groups mean square. Effect sizes should be comparable across different kinds of treatments and experimental designs. In the gender experiment, use of the square root of the total mean square to estimate σ gives an effect size that is comparable to those for treatments that are manipulated. The problem of estimating σ is exacerbated when the experiment has several treatments, repeated measures, and covariates. Gillett [27] and Olejnik and Algina [57] provide guidelines for computing effect sizes for such designs.

There are other problems with estimators of δ . For example, the three estimators, d , g' , and g , assume normality and a common standard deviation. Unfortunately, the value of the estimators is greatly affected by heavy-tailed distributions and heterogeneous standard deviations [82]. Considerable research has focused on ways to deal with these problems [6, 44, 49, 50, 82, 83]. Some solutions attempt to improve the estimation of δ , other solutions call for radically different ways of conceptualizing effect magnitude. In the next section, measures that represent the proportion of variance in the dependent variable that is explained by the variance in the independent variable are described.

Strength of Association

Another way to supplement null-hypothesis significance tests and help researchers assess the practical significance of research results is to provide a measure of the strength of the association between the independent and dependent variables. A variety of measures of strength of association are described by Carroll and Nordholm [6] and Särndal [70]. Two popular measures are omega squared, denoted by ω^2 , for a fixed-effects (see **Fixed and Random Effects**) treatment and the **intraclass correlation** denoted by ρ_1 , for a random-effects (see **Fixed and Random Effects**) treatment. A fixed-effects treatment is one in which all treatment levels about which inferences

are to be drawn are included in the experiment. A random-effects treatment is one in which the p treatment levels in the experiment are a random sample from a much larger population of P levels. For a completely randomized analysis of variance design, omega squared and the intraclass correlation are defined as

$$\frac{\sigma_{\text{Treat}}^2}{\sigma_{\text{Treat}}^2 + \sigma_{\text{Error}}^2},$$

where σ_{Treat}^2 and σ_{Error}^2 denote respectively the treatment and error variance. Both omega squared and the intraclass correlation represent the proportion of the population variance in the dependent variable that is accounted for by specifying the treatment-level classification. The parameters σ_{Treat}^2 and σ_{Error}^2 for a completely randomized design are generally unknown, but they can be estimated from sample data. Estimators of ω^2 and ρ_I are respectively

$$\begin{aligned}\hat{\omega}^2 &= \frac{SS_{\text{Treat}} - (p-1)MS_{\text{Error}}}{SS_{\text{Total}} + MS_{\text{Error}}} \\ \hat{\rho}_I &= \frac{MS_{\text{Treat}} - MS_{\text{Error}}}{MS_{\text{Treat}} + (n-1)MS_{\text{Error}}},\end{aligned}\quad (10)$$

where SS denotes a sum of squares, MS denotes a mean square, p denotes the number of levels of the treatment, and n denotes the number of observations in each treatment level. Omega squared and the intraclass correlation are biased estimators because they are computed as the ratio of unbiased estimators. The ratio of unbiased estimators is, in general, not an unbiased estimator. Carroll and Nordholm (1975) showed that the degree of bias in $\hat{\omega}^2$ is slight.

The usefulness of Cohen's δ was enhanced because he suggested guidelines for its interpretation. On the basis of Cohen's [12] classic work, the following guidelines are suggested for interpreting omega squared:

$$\begin{aligned}\omega^2 = 0.010 &\text{ is a small association} \\ \omega^2 = 0.059 &\text{ is a medium association} \\ \omega^2 = 0.138 \text{ or larger} &\text{ is a large association.}\end{aligned}\quad (11)$$

According to Sedlmeier and Gigerenzer [72] and Cooper and Findley [16], the typical strength of association in the journals that they examined was around 0.06—a medium association.

Omega squared and the intraclass correlation, like the measures of effect size, have their critics. For

example, O'Grady [56] observed that $\hat{\omega}^2$ and $\hat{\rho}_I$ may underestimate the true proportion of explained variance. If, as is generally the case, the dependent variable is not perfectly reliable, measurement error will reduce the proportion of variance that can be explained. Years ago, Gulliksen [33] pointed out that the absolute value of the product-moment correlation coefficient, r_{XY} , cannot exceed $(r_{XX'})^{1/2} (r_{YY'})^{1/2}$, where $r_{XX'}$ and $r_{YY'}$ are the reliabilities of X and Y . O'Grady [56] also criticized omega squared and the intraclass correlation on the grounds that their value is affected by the choice and number of treatment levels. As the diversity and number of treatment levels increases, the value of measures of strength of association also tends to increase. Levin [52] criticized $\hat{\omega}^2$ on the grounds that it is not very informative when an experiment contains more than two treatment levels. A large value of $\hat{\omega}^2$ simply indicates that the dependent variable for at least one treatment level is substantially different from the other levels. As is true for all omnibus measures, $\hat{\omega}^2$ and $\hat{\rho}_I$ do not pinpoint which treatment level(s) is responsible for a large value.

The last criticism can be addressed by computing omega squared and the intraclass correlation for two-mean contrasts as is typically done with Hedges' g_c . This solution is in keeping with the preference of many researchers to ask focused one-degree-of-freedom questions of their data [41, 66] and the recommendation of the *Publication Manual of the American Psychological Association* [1, p. 26], 'As a general rule, multiple degree-of-freedom effect indicators tend to be less useful than effect indicators that decompose multiple degree-of-freedom tests into meaningful one-degree-of-freedom effects – particularly when these are the results that inform the discussion.'

The formulas for omega squared and the intraclass correlation can be modified to give the proportion of variance in the dependent variable that is accounted for by the i th contrast, $\hat{\psi}_i$. The formulas for a completely randomized design are

$$\begin{aligned}\hat{\omega}_{Y|\psi_i}^2 &= \frac{SS \hat{\psi}_i - MS_{\text{Error}}}{SS_{\text{Total}} + MS_{\text{Error}}} \\ \hat{\rho}_{IY|\psi_i} &= \frac{SS \hat{\psi}_i - MS_{\text{Error}}}{SS \hat{\psi}_i + (n-1)MS_{\text{Error}}},\end{aligned}\quad (12)$$

where $SS \hat{\psi}_i = \hat{\psi}_i^2 / \sum_{j=1}^p c_j^2 / n_j$ and the c_j s are coefficients that define the contrast [45]. These measures

6 Effect Size Measures

answer focused one-degree-of-freedom questions as opposed to omnibus questions about one's data.

To determine the strength of association in experiments with more than one treatment or experiments with a blocking variable, partial omega squared can be computed. A comparison of omega squared and partial omega squared for treatment A for a two-treatment, completely randomized factorial design is

$$\omega_{Y|A}^2 = \frac{\sigma_A^2}{\sigma_A^2 + \sigma_B^2 + \sigma_{AB}^2 + \sigma_{\text{Error}}^2}$$

and

$$\omega_{Y|A \cdot B, AB}^2 = \frac{\sigma_A^2}{\sigma_A^2 + \sigma_{\text{Error}}^2}, \quad (13)$$

where partial omega squared ignores treatment B and the $A \times B$ interaction. If one or more of the variables in a multitreatment experiment is an organismic or blocking variable, Olejnik and Algina [58] show that partial omega squared is not comparable across different experimental designs. Furthermore, Cohen's guidelines for small, medium, and large effects are not applicable. They propose a measure of strength of association called *generalized omega squared*, denoted by ω_G^2 , that is appropriate, and they provide extensive formulas for its computation.

Meta-analysts often use the familiar product-moment correlation coefficient, r , to assess strength of association. The square of r called the *coefficient of determination* indicates the sample proportion of variance in the dependent variable that is accounted for by the independent variable. The product-moment

correlation and its close relatives can be used with a variety of variables:

Product-moment correlation	X and Y are continuous and linearly related
phi correlation, ϕ	X and Y are dichotomous
Point-biserial correlation, r_{pb}	X is dichotomous, Y is continuous
Spearman rank correlation, r_s	X and Y are in rank form.

The point-biserial correlation coefficient is particularly useful for answering focused questions. The independent variable is coded 0 and 1 to indicate the treatment level to which each observation belongs.

Two categories of measures of effect magnitude, measures of effect size and strength of association, have been described. Researchers are divided in their preferences for the two kinds of measures. As Table 2 shows, it is a simple matter to convert from one measure to another. Table 2 also gives formulas for converting the t statistic found in research reports into each of the measures of effect magnitude.

Other Measures of Effect Magnitude

Researchers continue to search for ways to supplement the null-hypothesis significance test and obtain a better understanding of their data. Their primary focus has been on measures of effect size and strength of association. But, as Table 1 shows, there are many other ways to measure effect magnitude. Some of the statistics in the 'Other measures' column of Table 1 are radically different from anything described thus

Table 2 Conversion formulas for four measures of effect magnitude

	t	g	r_{pb}	$\hat{\omega}_{Y \psi_i}^2$	$\hat{\rho}_{1 \psi_i}$
g	$t\sqrt{\frac{2}{n}}$		$\sqrt{\frac{r_{pb}^2 df 2n}{n^2(1-r_{pb}^2)}}$	$\sqrt{\frac{2(\hat{\omega}^2 - 2n\hat{\omega}^2 - 1)}{n(\hat{\omega}^2 - 1)}}$	$\sqrt{\frac{2(\hat{\rho}_1 - n\hat{\rho}_1 - 1)}{n(\hat{\rho}_1 - 1)}}$
r_{pb}	$\frac{t}{\sqrt{t^2 + df}}$	$\sqrt{\frac{g^2 n^2}{g^2 n^2 + df 2n}}$		$\sqrt{\frac{\hat{\omega}^2(1 - 2n) - 1}{\hat{\omega}^2(1 - 2n) + df(\hat{\omega}^2 - 1) - 1}}$	$\sqrt{\frac{\hat{\rho}_1(1 - n) - 1}{\hat{\rho}_1(1 - n) + df(\hat{\rho}_1 - 1) - 1}}$
$\hat{\omega}_{Y \psi_i}^2$	$\frac{t^2 - 1}{t^2 + 2n - 1}$	$\frac{ng^2 - 2}{ng^2 + 4n - 2}$	$\frac{r_{pb}^2(df + 1) - 1}{r_{pb}^2 df + (1 - r_{pb}^2)(2n - 1)}$		$\frac{\hat{\rho}_1}{2 - \hat{\rho}_1}$
$\hat{\rho}_{1 \psi_i}$	$\frac{t^2 - 1}{t^2 + n - 1}$	$\frac{ng^2 - 2}{ng^2 + 2n - 2}$	$\frac{r_{pb}^2(df + 1) - 1}{r_{pb}^2 df + (1 - r_{pb}^2)(n - 1)}$	$\frac{2\hat{\omega}^2}{\hat{\omega}^2 + 1}$	

far. One such measure for the two-group case is the *probability of superiority*, denoted by PS [31]. PS is the probability that a randomly sampled member of a population given one treatment level will have a score, Y_1 , that is superior to the score, Y_2 , of a randomly sampled member of another population given the other treatment level. The measure is easy to compute: $PS = U/n_1n_2$, where U is the Mann–Whitney statistic (see **Wilcoxon–Mann–Whitney Test**) and n_1 and n_2 are the two sample sizes. The value of U indicates the number of times that the n_1 participants who are given treatment level 1 have scores that outrank those of the n_2 participants who are given treatment level 2, assuming no ties or an equal allocation of ties. An unbiased estimator of the population $Pr(Y_1 > Y_2)$ is obtained by dividing U by n_1n_2 , the number of possible comparisons of the two treatment levels. An advantage of PS according to Grissom [31] is that it does not assume equal variances and is robust to nonnormality.

The **odds ratio** is another example of a different way of assessing effect magnitude. It is applicable to two-group experiments when the dependent variable has only two outcomes, say, success and failure. The term *odds* is frequently used by those who place bets on the outcomes of sporting events. The odds that an event will occur are given by the ratio of the probability that the event will occur to the probability that the event will not occur. If an event can occur with probability p , the odds in favor of the event are $p/(1 - p)$ to 1. For example, suppose an event occurs with probability $3/4$, the odds in favor of the event are $(3/4)/(1 - 3/4) = (3/4)/(1/4) = 3$ to 1.

The computation of the odds ratio is illustrated using the data in Table 3 where the performance of participants in the experimental and control groups is classified as either a success or a failure. For participants in the experimental group, the odds of success are

$$Odds(\text{Success}|\text{Exp. Grp.}) = \frac{n_{11}/(n_{11} + n_{12})}{n_{21}/(n_{21} + n_{22})}$$

$$= \frac{n_{11}}{n_{12}} = \frac{43}{7} = 6.1429. \quad (14)$$

For participants in the control group, the odds of success are

$$\begin{aligned} Odds(\text{Success}|\text{Control Grp.}) &= \frac{n_{21}/(n_{21} + n_{22})}{n_{22}/(n_{21} + n_{22})} \\ &= \frac{n_{21}}{n_{22}} = \frac{27}{23} = 1.1739. \end{aligned} \quad (15)$$

The ratio of the two odds is the odds ratio, $\hat{\omega}$,

$$\begin{aligned} \hat{\omega} &= \frac{Odds(\text{Success}|\text{Exp. Grp.})}{Odds(\text{Success}|\text{Control Grp.})} \\ &= \frac{n_{11}/n_{12}}{n_{21}/n_{22}} = \frac{n_{11}n_{22}}{n_{12}n_{21}} = 5.233. \end{aligned} \quad (16)$$

In this example, the odds of success for participants in the experiment group are approximately 5 times greater than the odds of success for participants in the control group. When there is no difference between the groups in terms of odds of success, the two rows (or two columns) are proportional to each other and $\hat{\omega} = 1$. The more the groups differ, the more $\hat{\omega}$ departs from 1. A value of $\hat{\omega}$ less than 1 indicates reduced odds of success for the experimental participants; a value greater than 1 indicates increased odds of success for the experimental participants. The lower bound for $\hat{\omega}$ is 0 and occurs when $n_{11} = 0$; the upper bound is arbitrarily large, in effect infinite, and occurs when $n_{21} = 0$.

The probability distribution of the odds ratio is positively skewed. In contrast, the probability distribution of the natural log of $\hat{\omega}$, $\ln \hat{\omega}$, is more symmetrical. Hence, when calculating a confidence interval for $\hat{\omega}$, it is customary to use $\ln \hat{\omega}$ instead of $\hat{\omega}$. A $100(1 - \alpha)$ confidence interval for $\ln \omega$ is given by

$$\ln \hat{\omega} - z_{\alpha/2} \hat{\sigma}_{\ln \hat{\omega}} < \ln \omega < \ln \hat{\omega} + z_{\alpha/2} \hat{\sigma}_{\ln \hat{\omega}},$$

Table 3 Classification of participants

	Success	Failure	Total
Experimental group	$n_{11} = 43$	$n_{12} = 7$	$n_{11} + n_{12} = 50$
Control group	$n_{21} = 27$	$n_{22} = 23$	$n_{21} + n_{22} = 50$
Total	$n_{11} + n_{21} = 70$	$n_{12} + n_{22} = 30$	

8 Effect Size Measures

where $z_{\alpha/2}$ denotes the two-tailed critical value that cuts off the upper $\alpha/2$ region of the standard normal distribution and $\hat{\sigma}_{\ln \hat{\omega}}$ denotes the standard error of $\ln \hat{\omega}$ and is given by

$$\hat{\sigma}_{\ln \hat{\omega}} = \sqrt{\frac{1}{n_{11}} + \frac{1}{n_{12}} + \frac{1}{n_{21}} + \frac{1}{n_{22}}}. \quad (17)$$

Once the lower and upper bounds of the confidence interval are found, the values are exponentiated to find the confidence interval for ω . The computation will be illustrated for the data in Table 3 where $\hat{\omega} = 5.233$. For $\hat{\omega} = 5.233$, $\ln \hat{\omega} = 1.6550$. A 100(1 - 0.05)% confidence interval for $\ln \omega$ is

$$\begin{aligned} 1.6550 - 1.96(0.4966) &< \ln \omega \\ &< 1.6550 + 1.96(0.4966) \\ 0.6817 &< \ln \omega < 2.6283. \end{aligned}$$

The confidence interval for ω is

$$\begin{aligned} e^{0.6817} &< \omega < e^{2.6283} \\ 2.0 &< \omega < 13.9 \end{aligned}$$

The researcher can be 95% confident that the odds of success for participants in the experiment group are between 2.0 and 13.9 times greater than the odds of success for participants in the control group. Notice that the interval does not include 1. The odds ratio is widely used in the medical sciences, but less often in the behavioral and social sciences. Table 1 provides references for a variety of other measures of effect magnitude. Space limitations preclude an examination of other potentially useful measures of effect magnitude.

From the foregoing, the reader may have gotten the impression that small effect magnitudes are never or rarely ever important or useful. This is not true. Prentice and Miller [60] and Spencer [74] provide numerous examples in which small effect magnitudes are both theoretically and practically significant. The assessment of practical significance always involves a judgment in which a researcher must calibrate the magnitude of an effect by the benefit possibly accrued from that effect [46].

Eigenvalue/Eigenvector

The terms eigenvalue and eigenvector are frequently encountered in **multivariate analysis** in particular in computer software that implements multivariate methods (see **Software for Statistical Analyses**). The reason for the widespread appearance of the terms is that many multivariate techniques reduce to finding the maximum or minimum of some quantity, and optimization of the quantity is achieved by solving what is known as an *eigenproblem*. Any $(p \times p)$ matrix has associated with it a set of p eigenvalues (not necessarily all distinct), which are scalars, and associated with each eigenvalue is its eigenvector, a vector of length p . Note that there are a number of alternative terminologies, including *latent roots/latent vectors*, *characteristic roots/vectors* and *proper values/vectors*. We discuss the general mathematical form of eigenproblems later, but start by explaining eigenvectors and eigenvalues in perhaps their most common statistical context, **principal component analysis**.

In principal component analysis, suppose we have n measurements on a vector $\mathbf{x}$ of p random variables. If p is large, it may be possible to derive a smaller number, q , of linear combinations of the variables in $\mathbf{x}$ that retain most of the variation in the full data set. Principal component analysis formalizes this by finding linear combinations, $\mathbf{a}_1'\mathbf{x}, \mathbf{a}_2'\mathbf{x}, \dots, \mathbf{a}_q'\mathbf{x}$, called *principal components*, that successively have maximum variance for the data, subject to being uncorrelated with previous $\mathbf{a}_k'\mathbf{x}$ s. Solving this maximization problem, we find that the vectors $\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_q$ are the eigenvectors, corresponding to the q largest eigenvalues, of the **covariance matrix** $\mathbf{S}$, of the data. Thus, in these circumstances, eigenvectors provide vectors of coefficients, weights or loadings that define the principal components in terms of the p original

variables. The eigenvalues also have a straightforward interpretation in principal component analysis, namely, they are the variances of their corresponding components.

Eigenvalues and eigenvectors also appear in other multivariate techniques. For example, in **discriminant analysis** those linear functions of $\mathbf{x}$ are found that best separate a number of groups, in the sense of maximizing the ratio of ‘between group’ to ‘within group’ variability for the linear functions. The coefficients of the chosen linear functions are derived as eigenvectors of $\mathbf{B}\mathbf{W}^{-1}$, where $\mathbf{B}$, $\mathbf{W}$ are matrices of between- and within-group variability for the p variables. A second example (there are many others) is **canonical correlation analysis**, in which linear functions of two sets of variables $\mathbf{x}_1, \mathbf{x}_2$ are found that have maximum correlation. The coefficients in these linear functions are once again derived as eigenvectors of a product of matrices. In this case, the elements of the matrices are variances and covariances for $\mathbf{x}_1$ and $\mathbf{x}_2$. The corresponding eigenvalues give squared correlations between the pairs of linear functions.

Finally, we turn to the mathematical definition of eigenvalues and eigenvectors. Consider a $(p \times p)$ matrix $\mathbf{S}$, which in the context of the multivariate techniques noted above often (though not always) consists of variances, covariances, or correlations. A vector $\mathbf{a}$ is an eigenvector of $\mathbf{S}$, and l is the corresponding eigenvalue, if $\mathbf{S}\mathbf{a} = l\mathbf{a}$. Geometrically, this means that $\mathbf{a}$ is a direction that is unchanged by the linear operator $\mathbf{S}$. If $\mathbf{S}$ is symmetric, the eigenvalues are real, but otherwise they may be complex. The sum of the eigenvalues equals the trace of the matrix $\mathbf{S}$ (the sum of its diagonal elements) and the product of the eigenvalues is the determinant of the matrix.

Empirical Quantile–Quantile Plots

An empirical quantile–quantile (EQQ) plot provides a graphical comparison between measures of *location* (means and medians, for instance) and *spread* (standard deviations, variances, ranges, etc.) for two ordered sets of observations, hence the name of the plot, where **quantiles** are ordered values and *empirical* refers to the source of the data. What one has with an EQQ plot, therefore, is the graphical equivalent of significance tests of differences in location and spread. The display itself is a form of added value **scatterplot**, in which the x and y axes represent the ordered values of the two sets of data.

Interpreting the resulting graph is easiest if the axes are identical, since an essential part of the plot is a 45-degree *comparison line* running from the bottom left-hand corner (the origin) to the upper right-hand corner of the display. Decisions about the data are made with respect to this comparison line; for instance, are the data parallel to it, or coincident with it, or is the bulk of the data above or below it? Indeed, so much information can be extracted from an EQQ plot that it is helpful to provide a summary table of data/comparison line outcomes and their statistical interpretation (see Table 1).

Three example EQQ plots are shown below. The data are taken from Minitab's *Fish* and *Crowd*

Figure 1 EQQ plot of average nest-guarding times for male and female fish

datasets (the latter omitting one problematic pair of observations).

In Figure 1, the location measure (for example, the average) for the male fish guarding time is higher than the equivalent measure for the female fish, since all the data lie *below* the 45% comparison line. However, the spreads seem the same in each sample as the data are clearly parallel with the comparison line.

In Figure 2, the data are almost exactly coincident with the 45% comparison line, thus showing graphically that there are no differences in either location or spread of the estimates of the crowdedness of the room by male and female students.

Table 1 Interpreting an EQQ plot

Relationship of data to comparison line	Interpretation with respect to location and spread
Bulk of data lies ABOVE	Locations different; location of y variable higher than x variable
Bulk of data lies BELOW	Locations different; location of x variable higher than y variable
Data PARALLEL	No difference in spreads
Data NOT PARALLEL	Difference in spreads; if the data starts ABOVE the comparison line and crosses it, then y variable spread smaller than x 's; <i>vice versa</i> for data starting BELOW the line
Data BOTH not parallel AND lies above or below	Differences in BOTH locations AND spreads
Data COINCIDENT	No differences in locations or spreads; samples are basically identical

2 Empirical Quantile–Quantile Plots

Figure 2 EQQ plot of estimates by male and female students of the crowdedness of a room

Figure 3 EQQ plot of nest-fanning times by male and female fish

In Figure 3 we have the time taken by both male and female fishes fanning their nests in order to

increase the flow of oxygenated water over the eggs. Clearly, the average female-fanning times are longer than those of the males since all the data lie above the comparison line, but it is also the case that the plotted data are not parallel to the comparison line, thereby strongly suggesting a difference in spreads as well. Here the female times seem to show a considerably larger spread than those of the male fish. One way of seeing this is to mentally project the largest and smallest values from the plot onto the x - and y -axes, and note which cuts off the larger or smaller length.

Finally, EQQ plots are most useful when the samples are independent because the necessity to order the data discards any correlational information in dependent samples. It is also useful to have equal numbers in the samples, although an interpolation routine is offered by Chambers et al. to substitute for any missing values ([1], pp. 54–55; see also pp. 48–57 for more on EQQ plots).

Epistasis

Several biologically motivated definitions of epistasis exist [1, 2], however, most modern textbooks of genetics define epistasis to include any interaction between genes at different loci to produce effects which are different from that expected from the individual loci themselves. For example, seed capsules produced by the shepard's purse plant (*Bursa bursa-pastoris*) are normally triangular as a result of two separate dominant pathways. It is only when both pathways are blocked through the action of a double recessive that oval capsules are produced. Thus, crosses from plants that are doubly heterozygous produce triangular and oval shaped purses in the ratio 15:1 rather than the usual Mendelian ratio of 3:1 [10, 13].

Epistasis may also be defined in quantitative genetic terms [5]. In this case, epistasis refers to a deviation from additivity in the effect of alleles and genotypes at different loci with respect to their contribution to a quantitative phenotype [2, 5]. Although the biological and quantitative genetic definitions of epistasis are related, it is important to realize that they are not formally equivalent [2]. In terms of the standard biometrical model, epistasis may involve interactions between the additive and/or dominance effects at two or more loci. For example, in the case of two loci, there may be additive $\times$ additive interactions, additive $\times$ dominance interactions, and dominance $\times$ dominance interactions. As the number of loci contributing to the trait increases, the number of possible epistatic interactions increases rapidly also (i.e., three-way interactions, four-way interactions etc.). It is important to realize that choice of scale is important, since a trait that demonstrates epistasis on one scale may not show evidence of epistasis on another transformed scale and vice versa.

Whilst in the case of a single locus, the total genetic variance of a quantitative trait is simply the sum of the additive and dominance components of variance, when multiple loci are considered, the genetic variance may also contain additional components of variation due to epistasis. The proportion of genetic variance due to epistatic interactions is termed the *epistatic variance*. It is the residual genetic variance, which is unexplained by the additive and dominance components. Similar to other **variance components**, the epistatic variance is a property of

the particular population of interest being dependent on population parameters such as allele and multi-locus genotype frequencies. The interested reader is referred to any of the classic texts in quantitative genetics for a formal mathematical derivation of epistatic variance [3, 6, 7, 9].

It is impossible to estimate epistatic variance components using the classical twin study (see **Twin Designs**). Several large twin studies have yielded low correlations between dizygotic twins, which cannot be explained through the effect of genetic dominance alone [4]. While it is possible to resolve higher order epistatic effects through careful breeding studies in experimental organisms (e.g., *Nicotiana Rustica*, *Drosophila*), this is unrealistic in human populations for a number of reasons. First, the analysis of higher order epistatic interactions would yield more parameters than could ever be estimated from any set of relatives [4]. Second, the correlation between the different components would be so high as to make it impossible to resolve them reliably [4, 8, 14]. Finally, when gene frequencies are unequal, multiple sources of gene action contribute to the variance components making interpretation of these components in terms of the underlying gene action problematic [4, 9].

Finally, it is possible to fit a variety of linkage and association models which incorporate epistatic effects at measured loci [2]. For example, it is possible to fit a two-locus variance components linkage model which includes a component of variance due to additive $\times$ additive epistatic interactions (for an example of how to do this see [11]). Although the power to detect epistasis will in general be low, Purcell and Sham [12] make the valuable point that it is still possible to detect a quantitative trait locus (QTL), which has no main effect but interacts epistatically with another unmeasured locus using a single locus model. This is because allele-sharing variables, which index epistatic and non-epistatic effects, are correlated. In other words, a single locus model will soak up most of the variance due to epistatic effects even though the power to detect epistasis formally through a multi-locus model is low [12].

Equivalence Trials

Methods for statistical equivalence testing grew out of the need by the pharmaceutical industry to demonstrate the bioequivalence of drugs [1–3]. When the patent expires on a brand-name drug, other companies may file abbreviated applications with the Food and Drug Administration (FDA) for approval of a generic equivalent without full efficacy and safety testing. What is needed is evidence that the generic and brand-name products differ only to a clinically unimportant degree. This is known as *equivalence testing*. Furthermore, as the number of drugs proven to be effective increases, it becomes increasingly questionable whether new drugs can ethically be compared to a placebo (inactive control). In such cases, the researcher may wish to compare the new drug against one already proven to be safe and effective (positive control). The aim of such a study may not be to demonstrate the superiority of the test drug but rather simply to demonstrate that it is not clinically inferior to the proven one. This is known as *noninferiority testing*.

Classical approaches to hypothesis testing (*see Classical Statistical Inference: Practice versus Presentation*), which test the null hypothesis of exact equality, are inappropriate for the equivalence problem. A conclusion of no real difference based upon the lack of a statistically significant difference is based on insufficient evidence. The lack of statistical significance might merely be due to insufficient statistical **power** or to excessive measurement error. What is needed is a method that permits us to decide whether the difference between treatments is small enough to be safely ignored in practice.

Equivalence testing begins with the *a priori* statement of a definition of equivalence. This should correspond to the largest difference that can be considered unimportant for the substantive problem at hand. Equivalence margins then are defined, bounded by lower and upper end points Δ_1 and Δ_2 , respectively. These margins define the range of mean differences ($M_1 - M_2$) that will be considered equivalent. It is not necessary that $\Delta_2 = -\Delta_1$; a larger difference in one direction than the other is allowed. For equivalence testing, both lower and upper margins are needed, but for noninferiority testing only the lower margin is needed. Next, data are collected and

the $(1 - 2\alpha)$ **confidence interval** for the difference between treatment means is calculated. Equivalence is inferred if this confidence interval falls entirely within the equivalence margins.

Equivalence testing also may be accomplished by simultaneously performing two one-sided hypothesis tests (*see Directed Alternatives in Testing*). One test seeks to reject the null hypothesis that the mean difference is less than or equal to Δ_1 :

$$\begin{aligned} H_0: M_1 - M_2 &\leq \Delta_1 \\ H_A: M_1 - M_2 &> \Delta_1 \end{aligned} \quad (1)$$

The second test seeks to reject the null hypothesis that the mean difference is greater than or equal to Δ_2 :

$$\begin{aligned} H_0: M_1 - M_2 &\geq \Delta_2 \\ H_A: M_1 - M_2 &< \Delta_2 \end{aligned} \quad (2)$$

In other words, we test the composite null hypothesis that the mean difference falls outside the equivalence margins versus the composite alternative hypothesis that the mean difference falls within the margins. The type I error rate is not affected by performing two tests because they are disjoint. The method just described is referred to as *average bioequivalence testing* because only population means are considered. Other methods are available for population bioequivalence testing (comparability of available drugs that a physician could prescribe for an individual new patient) and individual bioequivalence testing (switchability of available drugs within an individual patient) [1].

Error Rates

As some recent histories [1, 2] of null hypothesis statistical significance testing (NHSST) confirm, contemporary NHSST practices are an amalgam of the contradictory philosophies espoused by **Sir Ronald Fisher** as against **Jerzy Neyman** and **Egon Pearson**. In the appendix to their chapter, Mulaik, Raju, and Harshman [4] provide a thoughtful summary of those arguments.

Within the contemporary amalgam of NHSST practices, today, most researchers acknowledge the possibility with sample data of rejecting a null hypothesis that in reality is true in the population. This mistake has come to be called a *Type I error*. Conversely, the failure to reject a null hypothesis when the null hypothesis is untrue in the population is called a *Type II error*. Of course, a given decision regarding a single null hypothesis cannot be both a Type I and a Type II error, and we can possibly make a Type I error only if we reject the null hypothesis (i.e., the result is ‘statistically significant’).

Unless we later collect data from the full population, we will never know for sure whether the decisions we take with sample data are correct, or the decisions are errors. However, we can mathematically estimate the probability of errors, and these can range between 0.0 and 1.0. Unless we are perverse scientists with an evil fascination with untruth, we prefer the probabilities of decision errors to be small (e.g., 0.01, 0.05, 0.10).

The ceiling we select as that maximum probability of a Type I error, called α or α_{TW} (e.g., $\alpha = 0.05$), on a given, single hypothesis test is called the *testwise error rate*. In other words, ‘error rate’ always refers only to Type I errors. (When researchers say only α , they are implicitly always referring to α_{TW} .)

However, when we test multiple hypotheses (see **Multiple Comparison Procedures**), the probability of making one or more Type I errors in the set of decisions, called the *experimentwise error rate* (α_{EW}), is not necessarily equal to the probability we select as the ceiling for testwise error rate (α_{TW}). The α_{EW} is always equal to or greater than the α_{TW} .

There are two situations in which in a given study $\alpha_{EW} = \alpha_{TW}$. First, if we conduct a study in which we test only a single hypothesis, then α_{EW} must equal α_{TW} . Second, if we test multiple hypotheses in which the outcome variables or the hypotheses are

perfectly correlated with each other, then α_{EW} still must equal α_{TW} .

For example, if we are investigating the effects of an intervention versus a control condition on self-concept, we might employ two different self-concept tests, because we are not totally confident that either test is perfect at measuring the construct. If it turned out that the two outcome variables were perfectly correlated, even if we performed two *t* Tests or two ANOVAs (analyses of variance) to analyze the data, the α_{EW} would still equal α_{TW} .

The previous example (correctly) suggests that the correlations of the outcome variables or the hypotheses impact the inflation of the testwise error rate (i.e., the experimentwise error rate). Indeed, α_{EW} is most inflated when the outcome variables or the hypotheses are perfectly uncorrelated. At this extreme, the formula due to Bonferroni can be used to compute the experimentwise error rate:

$$\alpha_{EW} = 1 - (1 - \alpha_{TW})^k, \quad (1)$$

where k equals the number of outcome variables or hypotheses tested.

Love [3] provides a mathematical proof that the Bonferroni formula is correct. If the outcome variables or hypotheses are neither perfectly correlated nor perfectly uncorrelated, α_{EW} is computationally harder to determine, but would fall within the range of α_{TW} to $[1 - (1 - \alpha_{TW})^k]$.

For example, at one extreme if we tested five perfectly correlated hypotheses, each at $\alpha_{TW} = 0.05$, then $\alpha_{EW} = \alpha_{TW} = 0.05$. At the other extreme, if the hypotheses or outcomes were perfectly uncorrelated, the Bonferroni formula applies, and α_{EW} would be

$$\begin{aligned} &1 - (1 - 0.05)^5 \\ &1 - (0.95)^5 \\ &1 - 0.774 = 0.226. \end{aligned} \quad (2)$$

In other words, if five uncorrelated hypotheses are tested, each at $\alpha_{TW} = 0.05$, then the probability of one or more Type I errors being made is 22.6%. Two very big problems with this disturbing result are that the probability does not tell us (a) exactly how many Type I errors (e.g., 1, 2, 3...) are being made or (b) where these errors are.

This is one reason why multivariate statistics are often necessary. If we test one multivariate

2 Error Rates

hypothesis, rather than conducting separate tests of the five outcome variables, $\alpha_{EW} = \alpha_{TW}$.

Years ago, researchers noticed that α_{EW} approximately equals $k(\alpha_{TW})$ (e.g., 22.6% approximately equals $5(0.05) = 25.0\%$). Thus was born the ‘Bonferroni correction’, which adjusts the original α_{TW} downward, so that given the new testwise alpha level (α_{TW}^*), the α_{EW} would be roughly equal to α_{TW} . With the present example, α_{TW}^* would be set equal to 0.01, because $\alpha_{TW} = 0.05/5$ is 0.01. However, one problem with using the Bonferroni correction in this manner is that although the procedure controls the experiment-wise Type I error rate, the probability of making Type II error gets correspondingly larger with this method.

One common application of the Bonferroni correction that is more appropriate involves *post hoc* tests in ANOVA. When we test whether the means of more than two groups are equal, and determine that some differences exist, the question arises as to exactly which groups differ. We address this question by invoking one of the myriad *post hoc* test procedures (e.g., Tukey, Scheffè, Duncan).

Post hoc tests always compare one mean versus a second mean. Because the differences in two means are being tested, *post hoc* tests invoke a variation on

the *t* Test invented by a Guinness brewery worker roughly a century ago. Conceptually, ANOVA *post hoc* tests (e.g., Tukey, Scheffè, Duncan) are *t* Tests with build in variations on the Bonferroni correction being invoked so as to keep α_{EW} from becoming too inflated.

Estimation

In the simplest case, a data set consists of observations on a single variable, say real-valued observations. Suppose there are n such observations, denoted by $X_1, \dots, X_n$. For example, X_i could be the reaction time of individual i to a given stimulus, or the number of car accidents on day i , and so on. Suppose now that each observation follows the same probability law P . This means that the observations are relevant if one wants to predict the value of a new observation X (say, the reaction time of a hypothetical new subject, or the number of car accidents on a future day, etc.). Thus, a common underlying distribution P allows one to generalize the outcomes.

The emphasis in this paper is on the data and estimators derived from the data, and less on the estimation of population parameters describing a model for P . This is because the data exist, whereas population parameters are a theoretical construct (see **Model Evaluation**). An estimator is any given function $T_n(X_1, \dots, X_n)$ of the data. Let us start with reviewing some common estimators.

The Empirical Distribution. The unknown P can be estimated from the data in the following way. Suppose first that we are interested in the probability that an observation falls in A , where A is a certain set chosen by the researcher. We denote this probability by $P(A)$. Now, from the frequentist point of view, a probability of an event is nothing else than the limit of relative frequencies of occurrences of that event as the number of occasions of possible occurrences n grows without limit. So, it is natural to estimate $P(A)$ with the frequency of A , that is, with

$$\begin{aligned} \hat{P}_n(A) &= \frac{\text{number of times an observation } X_i \text{ falls in } A}{\text{total number of observations}} \\ &= \frac{\text{number of } X_i \in A}{n}. \end{aligned} \quad (1)$$

We now define the empirical distribution $\hat{P}_n$ as the probability law that assigns to a set A the probability $\hat{P}_n(A)$. We regard $\hat{P}_n$ as an estimator of the unknown P .

The Empirical Distribution Function. The distribution function of X is defined as

$$F(x) = P(X \leq x), \quad (2)$$

and the empirical distribution function is

$$\hat{F}_n(x) = \frac{\text{number of } X_i \leq x}{n}. \quad (3)$$

Figure 1 plots the distribution function $F(x) = 1 - 1/x^2$, $x \geq 1$ (smooth curve) and the empirical distribution function $\hat{F}_n$ (stair function) of a sample from F with sample size $n = 200$.

Sample Moments and Sample Variance. The theoretical mean

$$\mu = E(X), \quad (4)$$

(E stands for *Expectation*), can be estimated by the sample average

$$\bar{X}_n = \frac{X_1 + \dots + X_n}{n}. \quad (5)$$

More generally, for $j = 1, 2, \dots$ the j th sample moment

$$\hat{\mu}_{j,n} = \frac{X_1^j + \dots + X_n^j}{n}, \quad (6)$$

is an estimator of the j th moment $E(X^j)$ of P (see **Moments**).

Figure 1 The empirical and theoretical distribution function

2 Estimation

The sample variance

$$S_n^2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X}_n)^2 \quad (7)$$

is an estimator of the variance $\sigma^2 = E(X - \mu)^2$.

Sample Median. The median of X is the value m that satisfies $F(m) = 1/2$ (assuming there is a unique solution). Its empirical version is any value $\hat{m}_n$ such that $\hat{F}_n(\hat{m}_n)$ is equal or as close as possible to $1/2$. In the above example $F(x) = 1 - 1/x^2$, so that the theoretical median is $m = \sqrt{2} = 1.4142$. In the ordered sample, the 100th observation is equal to 1.4166, and the 101th observation is equal to 1.4191. A common choice for the sample median is taking the average of these two values. This gives $\hat{m}_n = 1.4179$.

Parametric Models. The distribution P may be partly known beforehand. The unknown parts of P are called *parameters* of the model. For example, if the X_i are yes/no answers to a certain question (the binary case), we know that P allows only two possibilities, say 1 and 0 (yes = 1, no = 0). There is only one parameter, say the probability of a yes answer $\theta = P(X = 1)$. More generally, in a parametric model, it is assumed that P is known up to a finite number of parameters $\theta = (\theta_1, \dots, \theta_d)$. We then often write $P = P_\theta$. When there are infinitely many parameters (which is, for example, the case when P is completely unknown), the model is called nonparametric.

If $P = P_\theta$ is a parametric model, one can often apply the maximum likelihood procedure to estimate θ (see **Maximum Likelihood Estimation**).

Example 1 The time one stands in line for a certain service is often modeled as exponentially distributed. The random variable X representing the waiting time then has a density of the form

$$f_\theta(x) = \theta e^{-\theta x}, \quad x > 0, \quad (8)$$

where the parameter θ is the so-called *intensity* (a large value of θ means that - on average - the waiting time is short), and the maximum likelihood estimator of θ is

$$\hat{\theta}_n = \frac{1}{\bar{X}_n}. \quad (9)$$

Example 2 In many cases, one assumes that X is normally distributed. In that case there are two parameters: the mean $\theta_1 = \mu$ and the variance $\theta_2 = \sigma^2$. The maximum likelihood estimators of (μ, σ^2) are $(\hat{\mu}_n, \hat{\sigma}_n^2)$, where $\hat{\mu}_n = \bar{X}_n$ is the sample mean and $\hat{\sigma}_n^2 = \sum_{i=1}^n (X_i - \bar{X}_n)^2/n$.

The Method of Moments. Suppose that the parameter θ can be written as a given function of the moments $\mu_1, \mu_2, \dots$. The *methods of moments estimator* replaces these moments by their empirical counterparts $\hat{\mu}_{n,1}, \hat{\mu}_{n,2}, \dots$

Example 3 Vilfredo Pareto [2] noticed that the number of people whose income exceeds level x is often approximately proportional to $x^{-\theta}$, where θ is a parameter that differs from country to country. Therefore, as a model for the distribution of incomes, one may propose the Pareto density

$$f_\theta(x) = \frac{\theta}{x^{\theta+1}}, \quad x > 1. \quad (10)$$

When $\theta > 1$, one has $\theta = \mu/(\mu - 1)$. Hence, the method of moments estimator of θ is in this case $t_1(\hat{P}_n) = \bar{X}_n/(\bar{X}_n - 1)$. After some calculations, one finds that the maximum likelihood estimator of θ is $t_2(\hat{P}_n) = (n/\sum_{i=1}^n \log X_i)$. Let us compare these on the simulated data in Figure 1. We generated in this simulation a sample from the Pareto distribution with $\theta = 2$. The sample average turns out to be $\bar{X}_n = 1.9669$, so that the methods of moments estimate is 2.0342. The maximum likelihood estimate is 1.9790. Thus, the maximum likelihood estimate is a little closer to the true θ than the methods of moments estimate.

Properties of Estimators. Let $T_n = T_n(X_1, \dots, X_n)$ be an estimator of the real-valued parameter θ . Then it is desirable that T_n is in some sense close to θ . A minimum requirement is that the estimator approaches θ as the sample size increases. This is called *consistency*. To be more precise, suppose the sample $X_1, \dots, X_n$ are the first n of an infinite sequence $X_1, X_2, \dots$ of independent copies of X . Then T_n is called consistent if (with probability one)

$$T_n \rightarrow \theta \text{ as } n \rightarrow \infty. \quad (11)$$

Note that consistency of frequencies as estimators of probabilities, or means as estimators of expectations, follows from the (strong) **law of large numbers**.

The *bias* of an estimator T_n of θ is defined as its mean deviation from θ :

$$\text{bias}(T_n) = E(T_n) - \theta. \quad (12)$$

We remark here that the distribution of $T_n = T_n(X_1, \dots, X_n)$ depends on P , and, hence, on θ . Therefore, the expectation $E(T_n)$ depends on θ as well. We indicate this by writing $E(T_n) = E_\theta(T_n)$. The estimator T_n is called *unbiased* if

$$E_\theta(T_n) = \theta \text{ for all possible values of } \theta. \quad (13)$$

Example 4 Consider the estimators $S_n^2 = \sum_{i=1}^n (X_i - \bar{X})^2 / (n-1)$ and $\hat{\sigma}_n^2 = \sum_{i=1}^n (X_i - \bar{X})^2 / n$. Note that S_n^2 is larger than $\hat{\sigma}_n^2$, but that the difference is small when n is large. It can be shown that S_n^2 is an unbiased estimator of the variance $\sigma^2 = \text{var}(X)$. The estimator $\hat{\sigma}_n^2$ is biased: it underestimates the variance.

In many models, unbiased estimators do not exist. Moreover, it often heavily depends on the model under consideration, whether or not an estimator is unbiased. A weaker concept is *asymptotic unbiasedness* (see [1]).

The mean square error of T_n as estimator of θ is

$$\text{MSE}(T_n) = E(T_n - \theta)^2. \quad (14)$$

One may decompose the MSE as

$$\text{MSE}(T_n) = \text{bias}^2(T_n) + \text{var}(T_n), \quad (15)$$

where $\text{var}(T_n)$ is the variance of T_n .

Bias, variance, and mean square error are often quite hard to compute, because they depend on the distribution of all n observations $X_1, \dots, X_n$. However, one may use certain approximations for large sample sizes n . Under regularity conditions, the maximum likelihood estimator $\hat{\theta}_n$ of θ is asymptotically unbiased, with asymptotic variance $1/(nI(\theta))$, where $I(\theta)$ is the Fisher information in a single observation (see **Information Matrix**). Thus, maximum likelihood estimators reach the minimum variance bound asymptotically.

Histograms. Our next aim is estimating the density $f(x)$ at a given point x . The density is defined as the derivative of the distribution function F at x :

$$f(x) = \lim_{h \rightarrow 0} \frac{F(x+h) - F(x)}{h} = \lim_{h \rightarrow 0} \frac{P(x, x+h]}{h}. \quad (16)$$

Figure 2 Histogram with bandwidth $h = 0.5$ and true density

Here, $(x, x+h]$ is the interval with left endpoint x (not included) and right endpoint $x+h$ (included). Unfortunately, replacing P by $\hat{P}_n$ here does not work, as for h small enough, $\hat{P}_n(x, x+h]$ will be equal to zero. Therefore, instead of taking the limit as $h \rightarrow 0$, we fix h at a (small) positive value, called the *bandwidth*. The estimator of $f(x)$, thus, becomes

$$\hat{f}_n(x) = \frac{\hat{P}_n(x, x+h]}{h} = \frac{\text{number of } X_i \in (x, x+h]}{nh}. \quad (17)$$

A plot of this estimator at points $x \in \{x_0, x_0 + h, x_0 + 2h, \dots\}$ is called a **histogram**.

Example 3 continued Figure 2 shows the histogram, with bandwidth $h = 0.5$, for the sample of size $n = 200$ from the Pareto distribution with parameter $\theta = 2$. The solid line is the density of this distribution.

Minimum Chi-square. Of course, for real (not simulated) data, the underlying distribution/density is not known. Let us explain in an example a procedure for checking whether certain model assumptions are reasonable. Suppose that one wants to test whether data come from the exponential distribution with parameter θ equal to 1. We draw a histogram of the sample (sample size $n = 200$), with bandwidth $h = 1$ and 10 cells (see Figure 3). The cell counts are (151, 28, 4, 6, 1, 1, 4, 3, 1, 1). Thus, for example, the number of observations that falls in

Figure 3 Histogram with bandwidth $h = 1$, exponential and Pareto density

the first cell, that is, that have values between 0 and 1, is equal to 151. The cell probabilities are, therefore, (0.755, 0.140, 0.020, 0.030, 0.005, 0.005, 0.020, 0.015, 0.005, 0.005). Now, according to the exponential distribution, the probability that an observation falls in cell k is equal to $e^{-(k-1)} - e^{-k}$, for $k = 1, \dots, 10$. These cell probabilities are (.6621, .2325, .0855, .0315, .0116, .0043, .0016, .0006, .0002, .0001). Because the probabilities of the last four cells are very small, we merge them together. This gives cell counts $(N_1, \dots, N_7) = (151, 28, 4, 6, 1, 1, 4, 9)$ and cell probabilities $(\pi_1, \dots, \pi_7) = (.6621, .2325, .0855, .0315, .0116, .0043, .0025)$. To check whether the cell frequencies differ significantly from the hypothesized cell probabilities, we calculate Pearson's χ^2 . It is defined as

$$\chi^2 = \frac{(N_1 - n\pi_1)^2}{n\pi_1} + \dots + \frac{(N_7 - n\pi_7)^2}{n\pi_7}. \quad (18)$$

We write this as $\chi^2 = \chi^2(\text{exponential})$ to stress that the cell probabilities were calculated assuming the exponential distribution. Now, if the data are exponentially distributed, the χ^2 statistic is generally not too large. But what is large? Consulting a table of Pearson's χ^2 at the 5% significance level gives the critical value $c = 12.59$. Here we use 6 degrees of freedom. This is because there are $m = 7$ cell probabilities, and there is the restriction $\pi_1 + \dots + \pi_m = 1$, so we estimated $m - 1 = 6$ parameters. After some calculations, one obtains $\chi^2(\text{exponential}) = 168.86$. This exceeds the critical

value c , that is, $\chi^2(\text{exponential})$ is too large to support the assumption of the exponential distribution. In fact, the data considered here are the simulated sample from the Pareto distribution with parameter $\theta = 2$. We shifted this sample one unit to the left. The value of χ^2 for this (shifted) Pareto distribution is

$$\chi^2(\text{Pareto}) = 10.81. \quad (19)$$

This is below the critical value c , so that the test, indeed, does not reject the Pareto distribution. However, this comparison is not completely fair, as our decision to merge the last four cells was based on the exponential distribution, which has much lighter tails than the Pareto distribution.

In Figure 3, the histogram is shown, together with the densities of the exponential and Pareto distribution. Indeed, the Pareto distribution fits the data better in the sense that it puts more mass at small values.

Continuing with the test for the exponential distribution, we note that, in many situations, the intensity θ is not required to be fixed beforehand. One may use an estimator for θ and proceed as before, calculating χ^2 with the estimated value for θ . However, the critical values of the test then become smaller. This is because, clearly, estimating parameters using the sample means that the hypothesized distribution is pulled towards the sample. Moreover, when using, for example, maximum likelihood estimators of the parameters, critical values will in fact be hard to compute. The minimum χ^2 estimator overcomes this problem. Let $\pi_k(\vartheta)$ denote the cell probabilities when the parameter value is ϑ , that is, in the exponential case $\pi_k(\vartheta) = e^{-\vartheta(k-1)} - e^{-\vartheta k}$, $k = 1, \dots, m - 1$, and $\pi_m(\vartheta) = 1 - \sum_{k=1}^{m-1} \pi_k(\vartheta)$. The minimum χ^2 estimator $\hat{\theta}_n$ is now the minimizer over ϑ of

$$\left\{ \frac{(N_1 - n\pi_1(\vartheta))^2}{n\pi_1(\vartheta)} + \dots + \frac{(N_m - n\pi_m(\vartheta))^2}{n\pi_m(\vartheta)} \right\}. \quad (20)$$

The χ^2 test with this estimator for θ now has $m - 2$ degrees of freedom. More generally, the number of degrees of freedom is $m - 1 - d$, where d is the number of estimated free parameters when calculating cell probabilities. The critical values of the test can be found in a χ^2 table.

Sufficiency. A goal of statistical analysis is generally to summarize the (large) data set into a small

number of characteristics. The sample mean and sample variance are such summarizing statistics, but so is, for example, the sample median, and so on. The question arises, to what extent one can summarize data without throwing away information. For example, suppose you are given the empirical distribution function $\hat{F}_n$, and you are asked to reconstruct the original data $X_1, \dots, X_n$. This is not possible since the ordering of the data is lost. However, the index i of X_i is just a label: it contains no information about the distribution P of X_i (assuming that each observation X_i comes from the same distribution, and the observations are independent). We say that the empirical distribution $\hat{F}_n$ is *sufficient*. More generally, a statistic $T_n = T_n(X_1, \dots, X_n)$ is called *sufficient* for P if the distribution of the data given the value of T_n does not depend on P . For example, it can be shown that when P is the exponential distribution with unknown intensity, then the sample mean is sufficient. When P is the normal distribution with unknown mean and variance, then the sample mean and sample variance are sufficient. Cell counts are not sufficient when, for example, P is a continuous distribution. This is

because, if one only considers the cell counts, one throws away information on the distribution within a cell. Indeed, when one compares Figures 2 and 3 (recall that in Figure 3 we shifted the sample one unit to the left), one sees that, by using just 10 cells instead of 20, the strong decrease in the second half of the first cell is no longer visible.

Sufficiency depends very heavily on the model for P . Clearly, when one decides to ignore information because of a sufficiency argument, one may be ignoring evidence that the model's assumptions may be wrong. Sufficiency arguments should be treated with caution.

Eta and Eta Squared

Eta-squared (η^2) is an **effect size** measure (typically the effect of manipulations across several groups). When statistical models are fitted to observations, the fit of the model is crucial. There are three main sources of variance that can be calculated: the total variability in the observed data, the model variability (the variability that can be explained by the model fitted), and the residual or error variability (the variability unexplained by the model). If sums of squared errors are used as estimates of variability, then the total variability is the total sum of squared errors (SS_T), that is, calculate the deviation of each score from the mean of all scores (the grand mean), square it, and then add these squared deviations together:

$$SS_T = \sum_{i=1}^n (x_i - \bar{x}_{\text{grand}})^2. \quad (1)$$

This can also be expressed in terms of the variance of all scores: $SS_T = s_{\text{grand}}^2(N - 1)$.

Once a model has been fitted, this total variability can be partitioned into the variability explained by the model, and the error. The variability explained by the model (SS_M) is the sum of squared deviations of the values predicted by the model and the mean of all observations:

$$SS_M = \sum_{i=1}^n (\hat{x}_i - \bar{x}_{\text{grand}})^2. \quad (2)$$

Finally, the residual variability (SS_R) can be obtained through subtraction ($SS_R = SS_T - SS_M$), or for a more formal explanation, see [3].

In **regression models**, these values can be used to calculate the proportion of variance that the model explains (SS_M/SS_T), which is known as the coefficient of determination (R^2). Eta squared is the same but calculated for models on the basis of group means. The distinction is blurred because using group means to predict observed values is a special case of a regression model (see [1] and [3], and **generalized linear models (GLM)**).

As an example, we consider data from Davey et al. [2] who looked at the processes underlying Obsessive Compulsive Disorder by inducing negative, positive, or no mood in people and then asking

them to imagine they were going on holiday and to generate as many things as they could that they should check before they went away (see Table 1).

The total variability can be calculated from the overall variance and the total number of scores (30):

$$SS_T = s_{\text{grand}}^2(N - 1) = 21.43(30 - 1) = 621.47. \quad (3)$$

The model fitted to the data (the predicted values) is the group means. Therefore, the model sum of squares can be rewritten as:

$$SS_M = \sum_{i=1}^n (\bar{x}_i - \bar{x}_{\text{grand}})^2, \quad (4)$$

in which $\bar{x}_i$ is the mean of the group to which observation i belongs. Because there are multiple observations in each group, this can be simplified still further:

$$SS_M = \sum_{i=1}^k n_i (\bar{x}_i - \bar{x}_{\text{grand}})^2, \quad (5)$$

where k is the number of groups. We would get:

$$\begin{aligned} SS_M &= 10(12.60 - 9.43)^2 + 10(7.00 - 9.43)^2 \\ &\quad + 10(8.70 - 9.43)^2 \\ &= 164.87. \end{aligned} \quad (6)$$

Eta squared is simply:

$$\eta^2 = \frac{SS_M}{SS_T} = \frac{164.87}{621.47} = 0.27. \quad (7)$$

Table 1 Number of ‘items to check’ generated under different moods

	Negative	Positive	None
	7	9	8
	5	12	5
	16	7	11
	13	3	9
	13	10	11
	24	4	10
	20	5	11
	10	4	10
	11	7	7
	7	9	5
$\bar{X}$	12.60	7.00	8.70
s^2	36.27	8.89	5.57
Grand Mean = 9.43 Grand Variance = 21.43			

2 Eta and Eta Squared

The literal interpretation is that by fitting the group means to the data, 27% of the variability in the number of items generated can be explained. This is the percentage reduction in error (PRE). Eta squared is accurate and unbiased when describing the sample; however, it is biased as a measure of the effect size in the population because there is sampling error associated with each of the group means that is not reflected in η^2 . Finally, the unsquared Eta (η) can be thought of as the correlation coefficient associated with a curvilinear line connecting the group means. It should be apparent that when groups are unordered, this statistic is not particularly useful.

Ethics in Research

Integrity in conducting research is important to individual researchers, their institutional sponsors, and the public at large. The increasing importance of the pursuit of new knowledge that relies on systematic, empirical investigation has led to greater demands for accountability. Research helps people make sense of the world in which they live and the events they experience. The knowledge gained through psychological research has provided many practical benefits as well as invaluable insights into the causes of human behavior. Despite the obvious advantages of the knowledge provided by research, the process of conducting scientific research can pose serious ethical dilemmas. Because research is a complex process, well-intentioned investigators can overlook the interests of research participants, thereby causing harm to the participants, scientists, science, and society.

A Historical Review of Research Ethics

Regulations affecting the research process can be seen as early as the fourteenth century when Pope Boniface VIII prohibited the cutting up of dead bodies, which was necessary to prevent knights from boiling the bodies of their comrades killed in the Holy Land in order to send them home for burial. While the practice was unrelated to medical research, it nevertheless, had an affect on scientific inquiry for centuries. More systematic regulation of research came about partly because of the atrocities committed by Nazi investigators conducting concentration camp experiments. At the end of World War II, 23 Nazi researchers, mostly physicians, were tried before the Nuremberg Military Tribunal. At the trial, it was important for the prosecutors to distinguish between the procedures used in Nazi experiments and those used by US wartime investigators. To do this, the judges agreed on 10 basic principles for research using human participants. Many of the principles set forth in the Nuremberg Code continue to form the foundation for ethical practices used today, including voluntary consent of the human participant, the avoidance of unnecessary suffering or injury, limitations on the degree of risk allowed, and the opportunity for the research participant to withdraw. While these principles were considered

laudatory, many American investigators viewed them as relevant only to Nazi war crimes and the impact on American scientists was minimal.

In the United States, oversight has come about as a result of a history of ethical abuses and exploitation, including the infamous study at the Willowbrook State School for the Retarded where a mild strain of virus was injected into children in order to study the course of the disease under controlled conditions, and the well-publicized Tuskegee Syphilis Study during which African-American men infected with syphilis were denied actual treatment and told not to seek alternative treatment from outside physicians. Such studies have created reasonable doubt as to the benevolence and value of research, especially among members of groups who received unethical treatment.

Federal Regulation of Research

To address these ethical concerns, the National Commission for the Protection of Human Subjects of Biomedical and Behavior Research was created and is best known for the Belmont Report [6], which identifies three basic ethical principles and their application to research: respect for persons, beneficence, and justice. These principles form the basis for provisions related to procedures insuring informed consent, assessment of risk and potential benefits, and selection of participants. In response to the Belmont Report, federal regulation of research became more systematic. While the primary responsibility for the ethical treatment of participants remains with the individual investigator, research in the United States conducted by individuals affiliated with universities, schools, hospitals, and many other institutions is now reviewed by a committee of individuals with diverse backgrounds who examine the proposed research project for any breach of ethical procedures. These review committees, commonly called *Institutional Review Boards* (IRBs), were mandated by the National Research Act, Public Law 93-348, and require researchers to prepare an application or protocol describing various aspects of the research and to submit this protocol along with informed consent forms for approval prior to the implementation of a research project. The review of the proposed research by the IRB includes an examination of the procedure, the nature of the participants, and other relevant factors in the research design. The IRB also

identifies the relevant ethical issues that may be of concern and decides what is at stake for the participant, the researcher, and the institution with which the researcher is affiliated. If there are ethical concerns, the IRB may suggest alternatives to the proposed procedures. Finally, the IRB will provide the researcher with a formal statement of what must be changed in order to receive IRB approval of the research project.

The attempt by IRBs to ensure ethical practices has caused some dissatisfaction among scientists. Since IRBs are not federal agencies but are instead created by local institutions, they have come under criticism for (a) lack of standard procedures and requirements; (b) delays in completing the review process; (c) creating the fear that IRBs will impose institutional sanctions on individual researchers; and (d) applying rules originally designed for medical studies to behavioral science research projects without acknowledging the important differences between the two. To address these concerns, IRBs should require both board members and principal investigators to undergo training in research ethics, adopt more consistent guidelines for evaluating research protocols, place limits on the power given to the IRB, include an evaluation of the technical merit of a proposal as a means of determining risk/benefit ratios, develop a series of case studies to help sensitize members of an IRB to ethical dilemmas within the social sciences and ways they may be resolved, encourage the recruitment of women, minorities, and children as research participants, adopt provisions that ensure students be given alternatives to participation in research when the research is a class requirement, and carefully review cases where a financial conflict of interest may occur [7].

Ethical Concerns in Recruiting Participants

One of the first ethical issues a researcher must address involves the recruitment of research participants. In the recruitment process, researchers must be guided by the principles of autonomy, respect for persons, and the principle of beneficence that requires that researchers minimize the possible harm to participants while maximizing the benefits from the research. The first stage in the recruitment of participants is often an advertisement for the research project. The advertisement generally describes the

basic nature of the research project and the qualifications that are needed to participate. At this stage, ethical concerns include the use of inducements and coercion, consent and alternatives to consent, institutional approval of access to participants, and rules related to using student subject pools [1]. It is important that researchers avoid ‘hyperclaiming,’ in which the goals the research is likely to achieve are exaggerated. It is also important that researchers not exploit potential participants, especially vulnerable participants, by offering inducements that are difficult to refuse. At the same time, researchers must weigh the costs to the participant and provide adequate compensation for the time they spend in the research process.

Most psychological research is conducted with students recruited from university subject pools, which raises an ethical concern since the students’ grades may be linked with participation. Ethical practice requires that students be given a reasonable alternative to participation in order to obtain the same credit as those who choose to participate in research. The alternatives offered must not be seen by students as either punitive or more stringent than research participation.

In the recruitment process, researchers should attempt to eliminate any potential participants who may be harmed by the research. Research protocols submitted to an IRB typically have a section in which the researcher describes this screening process and the criteria that will be used to include or exclude persons from the study. The screening process is of particular importance when using proxy decisions for incompetent persons and when conducting clinical research. On the other hand, it is important that the sample be representative of the population to which the research findings can be generalized.

Informed Consent and Debriefing

Informed consent is the cornerstone of ethical research. Consent can be thought of as a contract in which the participant agrees to tolerate experimental procedures that may include boredom, deception, and discomfort for the good of science, while the researcher guarantees the safety and well-being of the participant. In all but minimal-risk research, informed consent is a formal process whereby the relevant aspects of the research are described along with the obligations and responsibilities of both the participant

and the researcher. An important distinction is made between 'at risk' and 'minimal risk.' Minimal risk refers to a level of harm or discomfort no greater than that which the participant might expect to experience in daily life. Research that poses minimal risk to the participant is allowed greater flexibility with regard to informed consent, the use of deception, and other ethically questionable procedures. Although, it should still meet methodological standards to ensure that the participants' time is not wasted.

Informed consent presents difficulties when the potential participants are children, the participants speak a different language than the experimenter, or the research is therapeutic but the participants are unable to provide informed consent. Certain research methodologies make it difficult to obtain informed consent, as when the methodology includes disguised observation or other covert methods. The omission of informed consent in covert studies can be appropriate when there is a need to protect participants from nervousness, apprehension, and in some cases criminal prosecution. Studies that blur the distinction between consent for treatment or therapy and consent for research also pose ethical problems as can the use of a consent form that does not provide the participant with a true understanding of the research. While most psychological research includes an informed consent process, it should be noted that federal guidelines permit informed consent to be waived if (a) the research involves no more than minimal risk to the participants; (b) the waiver will not adversely affect the rights and welfare of the participants; and (c) the research could not be feasibly conducted if informed consent were required [4].

The Use of Deception in Psychological Research

At one time, deception was routinely practiced in behavioral science research, and by the 1960s research participants, usually college students, expected deception and as a result sometimes produced different results than those obtained from unsuspecting participants. In general, psychologists use deception in order to prevent participants from learning the true purpose of the study, which might in turn affect their behavior. Many forms of deception exist, including the use of an experimental confederate posing as another participant, providing false feedback to participants, presenting two related studies as unrelated,

and giving incorrect information regarding stimuli. The acceptability of deception remains controversial although the practice is common. Both participants and researchers tend to conduct a kind of cost-benefit analysis when assessing the ethics of deception. Researchers tend to be more concerned about the dangers of deception than do research participants. Participants' evaluation of studies that use deception are related to the studies' scientific merit, value, methodological alternatives, discomfort experienced by the participants, and the efficacy of the debriefing procedures.

Several alternatives to using deception are available. Role-playing and simulation can be used in lieu of deception. In field research, many researchers have sought to develop reciprocal relationships with their participants in order to promote acceptance of occasional deception. Such reciprocal relationships can provide direct benefits to the participants as a result of the research process. In cases where deception is unavoidable, the method of assumed consent can be used [3]. In this approach, a sample taken from the same pool as the potential participants is given a complete description of the proposed study, including all aspects of the deception, and asked whether they would be willing to participate in the study. A benchmark of 95% agreement allows the researcher to proceed with the deception manipulation.

Avoiding Harm: Pain and Suffering

Participants' consent is typically somewhat uninformed in order to obtain valid information untainted by knowledge of the researcher's hypothesis and expectations. Because of this lack of full disclosure, it is important that the researcher ensures that no harm will come to the participant in the research process. Protection from harm is a foundational issue in research ethics. Types of harm that must be considered by the researcher include physical harm, psychological stress, feelings of having one's dignity, self-esteem, or self-efficacy compromised, or becoming the subject of legal action. Other types of potential harm include economic harm, including the imposition of financial costs to the participants, and social harms that involve negative affects on a person's interactions or relationships with others. In addition to considering the potential harm that may accrue to the research participant, the possibility of harm to the

participants' family, friends, social group, and society must be considered.

While conducting research, it is the researcher's responsibility to monitor actual or potential harm to the participant in case the level of harm changes during the course of the research. One way that the level of potential harm can change is as a result of a mistake made by the researcher. In the case of increased likelihood of harm, the researcher should inform the participant and remind him or her that voluntary withdrawal without penalty is available.

A particular kind of harm addressed in the 1992 American Psychological Association (APA) Code of Ethics [2] is the harm caused by culturally incompetent researchers whose perceptions of gender and race are misinformed by the dominant group's view of social reality. Research designs constructed by researchers with uninformed views can reinforce negative stereotypes about the group studied. One way to avoid this ethical bias is to view research participants as partners as opposed to subjects in the research process. The perception of partnership can be fostered by taking the participants into the researchers' confidence, providing a thorough debriefing and the opportunity for further involvement in a role other than that of a 'subject.' Another type of harm, of special concern to those engaged in field research, is the harm that can result from disclosure of uncensored information.

While psychological research into certain processes, for example, anxiety, depends on the arousal of some discomfort in the participant, it is the responsibility of the researcher to look for ways to minimize this discomfort. In many situations, discomfort is inherent in what is being studied. When nothing can be done to eliminate this type of discomfort, some ways that may minimize the psychological consequences of the discomfort include full and candid disclosure of the experimental procedures, providing opportunities for the participant to withdraw, and ensuring that there are no lingering ill effects of the discomfort. One particular type of lingering ill effect relates to the possibility of embarrassment that participants can experience as a result of their behavior during the research process. To protect participants from this type of harm, it is essential that researchers employ procedures to maintain confidentiality.

Maintaining Confidentiality

Respecting the privacy of the research participant involves much more than just obtaining informed consent. Confidentiality is a complex, multifaceted issue. It involves an agreement, implicit as well as explicit, between the researcher and the participant regarding disclosure of information about the participant and how the participant's data will be handled and transmitted. The participant has the right to decide what information will be disclosed, to whom it will be disclosed, under what circumstances it will be disclosed, and when it will be disclosed.

Participants must be informed about mandatory reporting requirements, for example, illegal activity, plans for sharing information about the participant with others, and the extent to which confidentiality can be legally protected. It is the responsibility of review committees to ensure that the proposed research procedures will not unintentionally compromise confidentiality, especially with participants who are vulnerable because of age, gender, status, or disability.

There are exceptions to the rule regarding confidentiality. The 1992 APA Code of Ethics allows for a breach of confidentiality to protect third parties, and several states have embraced the Supreme Court ruling in *Tarasoff versus Board of Regents of the University of California* [9] that requires the psychologist to take reasonable steps to protect potential victims. Researchers not trained in clinical diagnosis can find themselves in a difficult position interpreting the likelihood of harm from statements made by research participants.

New technologies, along with government statutes and access by third parties to data, can threaten confidentiality agreements, although both state and federal courts have been willing to uphold promises of confidentiality made to research participants. Techniques to maintain confidentiality of data include data encryption and electronic security. While most quantified data are presented in aggregate form, some types of data such as video recordings, photographs, and audio recordings require special care in order to protect participants' privacy. Distortion of the images and sounds can be done, but the most important safeguard is to obtain permission from the participant to use the material, including the dissemination of the findings.

Similarly, qualitative research poses special difficulties for maintaining privacy and confidentiality. Techniques for maintaining confidentiality include the use of pseudonyms or fictitious biographies and the coding of tapes and other data recording methods in which participant identification cannot be disguised. Also, it is the researchers' responsibility to take reasonable precautions to ensure that participants respect the privacy of other participants, particularly in research settings where others are able to observe the behavior of the participant.

Assessing Risks and Benefits

One of the responsibilities of an IRB is to ask the question: will the knowledge gained from this research be worth the inconvenience and potential cost to the participant? Both the magnitude of the benefits to the participant and the potential scientific and social value of the research must be considered [5]. Some of the potential types of benefits of psychological research are (a) an increase in basic knowledge of psychological processes; (b) improved methodological and assessment procedures; (c) practical outcomes and benefits to others; (d) benefits for the researchers, including the educational functions of research in preparing students to think critically and creatively about their field; and (e) direct, sometimes therapeutic, benefits to the participants, for example, in clinical research.

Some of the potential costs to the participant are social and physical discomfort, boredom, anxiety, stress, loss of self-esteem, legal risks, economic risks, social risks, and other aversive consequences. In general, the risks associated with the research should be considered from the perspective of the participant, the researcher, and society as a whole, and should include an awareness that the risks to the participant may come not only from the research process, but also from particular vulnerabilities of the participant or from the failure of the researcher to use appropriate strategies to reduce risk.

The IRB's job of balancing these costs and benefits is difficult since the types of costs and benefits are so varied. The deliberations of the IRB in arriving at a 'favorable ratio' should be formed with respect to the guidelines provided in the Belmont Report, which encourages ethical review committees to examine all aspects of the research carefully and to

consider, on behalf of the researcher, alternative procedures to reduce risks to the participants. The careful deliberation of the cost/benefit ratio is of particular importance in research with those unable to provide informed consent, such as the cognitively impaired; research where there is risk without direct benefit to the participant, research with such vulnerable populations as children and adolescents; and therapeutic research in which the participant in need of treatment is likely to overestimate the benefit and underestimate the risk, even when the researcher has provided a full and candid description of the likelihood of success and possible deleterious effects.

Ethical Issues in Conducting Research with Vulnerable Populations

An important ethical concern considered by IRBs is the protection of those who are not able fully to protect themselves. While determining vulnerability can be difficult, several types of people can be considered vulnerable for research purposes, including people who (a) either lack autonomy and resources or have an abundance of resources, (b) are stigmatized, (c) are institutionalized, (d) cannot speak for themselves, (e) engage in illegal activities, and (f) may be damaged by the information revealed about them as a result of the research. One of the principle groups of research participants considered to be vulnerable is children and adolescents. In addition to legal constraints on research with minors adopted by the United States Department of Health and Human Services (DHHS), ethical practices must address issues of risk and maturity, privacy and autonomy, parental permission and the circumstances in which permission can be waived, and the assent of the institution (school, treatment facility) where the research is to be conducted.

Other vulnerable groups addressed in the literature include minorities, prisoners, trauma victims, the homeless, Alzheimer's patients, gays and lesbians, individuals with AIDS and STDs, juvenile offenders, and the elderly, particularly those confined to nursing homes where participants are often submissive to authority.

Research with psychiatric patients poses a challenge to the researcher. A major ethical concern with clinical research is how to form a control group without unethically denying treatment to some participants, for example, those assigned to a placebo

control group. One alternative to placebo-controlled trials is active-controlled trials.

A number of ethical issues arise when studying families at risk and spousal abuse. It is the responsibility of the investigator to report abuse and neglect, and participants must understand that prior to giving consent. Other ethical issues include conflict between research ethics and the investigator's personal ethics, identifying problems that cannot be solved, and balancing the demands made by family members and the benefits available to them.

Alcohol and substance abusers and forensic patients present particular problems for obtaining adequate informed consent. The researcher must take into account the participants' vulnerability to coercion and competence to give consent. The experience of the investigator in dealing with alcoholics and drug abusers can be an important element in maintaining ethical standards related to coercion and competence to give consent.

One final vulnerable population addressed in the literature is the cognitively impaired. Research with these individuals raises issues involving adult guardianship laws and the rules governing proxy decisions. The question is: who speaks for the participant? Research with vulnerable participants requires the researcher to take particular care to avoid several ethical dilemmas including coercive recruiting practices, the lack of confidentiality often experienced by vulnerable participants, and the possibility of a conflict of interest between research ethics and personal ethics.

Ethical Considerations Related to Research Methodology

Ethical Issues in Conducting Field Research

Research conducted in the field confronts an additional ethical dilemma not usually encountered in laboratory studies. Often the participants are unaware that they are being studied, and therefore no contractual understanding can exist. In many field studies, especially those that involve observational techniques, informed consent may be impossible to obtain. This dilemma also exists when the distinction between participant and observer is blurred. Similarly, some laboratory experiments involving deception use procedures similar to field research in introducing the independent variable as

unrelated to the experiment. Covert research that involves the observation of people in public places is not generally considered to constitute an invasion of privacy; however, it is sometimes difficult to determine when a reasonable expectation of privacy exists, for example, behavior in a public toilet.

Because it is not usually possible to assess whether participants have been harmed in covert studies, opinions regarding the ethicality and legality of such methods varies markedly. Four principles that must be considered in deciding on the ethicality of covert field research are (a) the availability of alternative means for studying the same question, (b) the merit of the research question, (c) the extent to which confidentiality or anonymity can be maintained, and (d) the level of risk to the uninformed participant.

One specific type of field research warrants special ethical consideration: socially sensitive research, which is defined as research where the findings can have practical consequences for the participants. The research question, the research process, and the potential application of the research findings are particularly important in socially sensitive research. IRBs have been found to be very wary of socially sensitive research, more often finding fault with the research and overestimating the extent of risk involved as compared to their reviews of less sensitive research. Despite these difficulties, socially sensitive research has considerable potential for addressing many of society's social issues and should be encouraged.

Ethical Issues in Conducting Archival Research

Archival research can provide methodological advantages to the researcher in that unobtrusive measures are less likely to affect how participants behave. However, research involving archival data poses a problem for obtaining informed consent, since the research question may be very different from the one for which the data was originally collected. In most cases, issues of privacy do not exist since an archive can be altered to remove identifying information. A second ethical concern with archival research has to do with the possibility that those who create the archive may introduce systematic bias into the data set. This is of particular concern when the archive is written primarily from an official point of view that may not accurately represent the participants' attitudes, beliefs, or behavior.

Ethical Issues in Conducting Internet Research

The Internet provides an international forum in which open and candid discussions of a variety of issues of interest to behavioral scientists take place (see **Internet Research Methods**). These discussions provide an opportunity for the behavioral scientist to 'lurk' among Usenet discussion groups, Internet Relay Chat, and Multiuser dungeons. Cyberspace is typically thought of as public domain where privacy is not guaranteed and traditional ethical guidelines may be difficult to apply. A second ethical concern in Internet research is the possibility for on-line misrepresentation. For example, children or other vulnerable populations could be inadvertently included in research. To address these concerns, a set of informal guidelines for acceptable behavior in the form of netiquettes has been developed. Among other things, the guidelines suggest that researchers should identify themselves, ensure confidential treatment of personal information, be sensitive to possible unanticipated consequences to participants as a result of the research process, particularly in terms of potential harm to the participant in the form of stress, legal liabilities, and loss of self-esteem, obtain consent from those providing data whenever possible, and provide participants with information about the study.

Debriefing

Debriefing provides the participant an opportunity to discuss the findings of the study. The need to adequately debrief participants in a research study is a clear ethical responsibility of the investigator although it is still the exception rather than the rule. Debriefing can serve four purposes. It can (a) remove fraudulent information about the participant given during the research process, (b) desensitize subjects who have been given potentially disturbing information about themselves, (c) remove the participants' negative arousal resulting from the research procedure, and (d) provide therapeutic or educational value to the participant. Even participants who are screened out of a study or voluntarily withdraw from a study should be debriefed and told why they might have been eliminated from the study. It has also been suggested that a description of the debriefing procedure be included in any scientific publication of the research.

The Use of Animals in Research

Animal research by psychologists can be dated back to rat maze studies at Clark University in 1901. Many medical breakthroughs including such procedures as chemotherapy, vaccines, bypass surgery, and antibiotics are based on animal studies. While animal research will remain controversial among many people, the first federal attempt to provide standards began with the Animal Welfare Act of 1966. Building upon this foundation, the American Psychological Association has also established ethical standards for the 'humane care and use of animals in research.' It is the responsibility of the research scientist to observe all appropriate laws and regulations and professional standards in acquiring, caring for, and disposing of animals. The research scientist must also ensure that those working with animals are trained and experienced in both research methods and animal care in order to provide for the comfort, health, and humane treatment of the animals. A third responsibility is to minimize the discomfort, infection, illness, and pain of the animals involved in research and to only subject animals to pain, stress, or privation when an alternative procedure is not available, and even then only when the potential value of the research makes the negative treatment justifiable. Scientists involved in surgical procedures with animals have a special responsibility to use appropriate anesthesia and procedures both during and after surgery in order to minimize pain and possible infection. Finally, when the life of a research animal is to be terminated, it must be done in a manner designed to minimize pain and observe accepted procedures. In order to promote and ensure the ethical treatment of animals in research, most research facilities and universities have animal review committees (IACUCs) that perform a function similar to the IRB. These committees can judge the adequacy of the procedures being proposed, the training and experience of the investigators, and whether nonanimal models could be used to answer the questions being posed.

Ethical Issues When the Research is Completed

Plagiarism occurs when an investigator uses the work of someone else without giving credit to the original author. There are several steps that the researcher can

take to avoid this ethical breach, including (a) careful acknowledgement of all sources, including secondary sources of information, (b) use of quotation marks to set off direct quotes and taking care that paraphrasing another author is not simply a minor variation of the author's own words, and (c) maintaining complete records of rough notes, drafts, and other materials used in preparing a report.

Several notorious cases, including that of Cyril Burt, have clearly demonstrated the ethical ban on the falsification and fabrication of data, as well as the misuse of statistics to mislead the reader. In addition to fabrication, it is unethical to publish, as original data, material that has been published before. It is also the ethical responsibility of the investigator to share research data for verification. While these are fairly straightforward ethical considerations, it is important to distinguish between honest errors and misconduct in statistical reporting. Currently, there are no federal guidelines that inform our understanding of the differences between common practices and actual misuse. Therefore, it is important that individual investigators consult with statisticians in order to apply the most appropriate tests to their data.

Authorship credit at the time of publication should only be taken for work actually performed and for substantial contributions to the published report. Simply holding an institutional position is not an ethical reason for being included as an author of a report. Students should be listed as the principal author of any article that is primarily based on that student's work, for example, a dissertation.

Summary and Conclusion

Ethical dilemmas often arise from a conflict of interest between the needs of the researcher and the needs of the participant and/or the public at large. A conflict of interest can occur when the researcher occupies multiple roles, for example, clinician/researcher, or within a single role such as a program evaluation researcher who experiences sponsor pressures for results that may compromise scientific rigor. In resolving ethical dilemmas, psychologists are guided in their research practices by APA guidelines as well as Federal regulations that mandate that research be approved by an Institutional Review Board or Institutional Animal Care and Use Committee. A set of

heuristics that can be employed in resolving ethical conflicts include: (a) using the ethical standards of the profession, (b) applying ethical and moral principles, (c) understanding the legal responsibilities placed upon the researcher, and (d) consulting with professional colleagues [8]. In the final analysis, the researcher's conscience determines whether the research is conducted in an ethical manner. To enhance the researcher's awareness of ethical issues, education and training programs have become increasingly available in university courses, workshops, and on governmental websites. The use of role-playing and context-based exercises, and the supervision of student research have been shown to effectively increase ethical sensitivity.

Evaluation Research

From a methodological standpoint, the most challenging task an evaluation researcher faces is determining a program's effects on the social conditions it is expected to ameliorate. This is also one of the most important tasks for the evaluator because a program that does not have the anticipated beneficial effects is unlikely to be viewed favorably, irrespective of how well it functions in other regards. Evaluation researchers refer to this form of evaluation as an impact evaluation or outcome evaluation. Because of the centrality of impact evaluation in evaluation research and its dependence on quantitative methods, it is our focus in this essay.

Impact Evaluation

The basic question asked by an impact evaluation is whether the program produces its intended effects. This is a causal question and the primary method for answering it is an experiment that compares the outcomes for an intervention condition to those from a control condition without the intervention. Evaluation research is conducted largely in field settings where 'true' experiments with random assignment and strict control of extraneous influences are difficult to achieve. Evaluation researchers, therefore, often fall back on quasi-experiments, (see **Quasi-experimental Designs**) most commonly nonequivalent comparison designs lacking random assignment [18]. The application of these designs to social programs raises a variety of methodological challenges. We turn now to some of the most salient of these challenges.

Outcome Measurement

No systematic assessment of a program's effects can be made unless the intended outcomes can be measured. Program representatives often describe the expected outcomes in broad terms (e.g., 'improve the quality of life for children') that must be unpacked to identify their specific observable features (e.g., improved health, cognitive development, and social relationships). A necessary first step, therefore, is usually a negotiation between the evaluator and the

program stakeholders to carefully specify the changes the program is expected to bring about and the indicators that signal whether they occurred. Once adequately specified, these outcomes can often be measured using established procedures; for example, standardized achievement tests and grade point averages are conventional measures of academic performance. However, there may be no established valid and reliable measures for some outcomes and the evaluator must then attempt to develop them.

In addition to validity and reliability, however, evaluators have to be concerned with another measurement characteristic – sensitivity, or the extent to which scores on a measure change when a change actually occurs on an outcome the program is attempting to affect. There are two main ways in which an outcome measure can be insensitive to change. First, the measure may include elements that relate to something other than what the program targets. Consider, for example, a math tutoring program concentrating on fractions and long division problems for elementary school children. The evaluator might choose an off-the-shelf math achievement test as an outcome measure even though it covers a wider selection of math problems than fractions and long division. Large gains in fractions and long division might be obscured by the response to other topics that are averaged into the final score. A measure that covered only the math topics that the program actually taught would be more sensitive to these gains.

Second, outcome measures may be insensitive to program effects if they have been developed to differentiate individuals for diagnostic purposes. Most standardized psychological tests are of this sort, including, for example, measures of personality traits, clinical symptoms, cognitive abilities, and attitudes. These measures are generally good for determining who is high or low on the characteristic measured. However, when applied to program participants who differ on the measured characteristic, they may yield such wide variation in scores that improvement due to the program is lost amid the differences among individuals.

Unit of Analysis

Social programs deliver their services to any of a wide variety of entities, such as individuals, families, schools, neighborhoods, or cities. Correspondingly,

the units in the research sample may be any of these entities. It is not unusual for the program to deliver its services to one level with the intent of producing effects on units nested within this level. This situation occurs frequently in educational programs. A mathematics curriculum, for instance, may be implemented school wide and delivered mainly at the classroom level. The desired outcome, however, is improved math achievement for the students in those classes. Students can be sampled only by virtue of being in a classroom that is, or is not, using the curriculum of interest. Thus, the classroom is the primary sampling unit but the students clustered within the classrooms are of focal interest for the evaluation and are the primary analysis unit.

A common error is to analyze the outcome data at the student level, ignoring the clustering of students within classrooms. This error exaggerates the sample size used in the statistical analysis by counting the number of students rather than the number of classrooms that are the actual sampling unit. It also treats the student scores within each classroom as if they were independent data points when, because of the students' common classroom environment and typically nonrandom assignment to classrooms, their scores are likely to be more similar within classrooms than they would be otherwise. This situation requires the use of specialized multilevel statistical analysis models (*see* **Linear Multilevel Models**) to properly estimate the standard errors and determine the statistical significance of any effects (for further details, see [13, 19].

Selection Bias

When an impact evaluation involves an intervention and control group that show preintervention differences on one or more variables related to an outcome of interest, the result is a postintervention difference that mimics a true intervention effect. Initial nonequivalence of this sort biases the estimate of the intervention effects and undermines the validity of the design for determining the actual program effects. This serious and unfortunately common problem is called *selection bias* because it occurs in situations in which units have been differentially selected into the intervention and control groups.

The best way to achieve equivalence between intervention and control groups is to randomly allocate members of a research sample to the groups (see [2] for a discussion of how to implement randomization) (*see* **Randomization**). However, when intervention and control groups cannot be formed through random assignment, evaluators may attempt to construct a matched control group by selecting either individuals or an aggregate group that is similar on a designated set of variables to those receiving the intervention. In individual **matching**, a partner is selected from a pool of individuals not exposed to the program who matches each individual who does receive the program. For children in a school drug prevention program, for example, the evaluator might deem the relevant matching variables to be age, sex, and family income. In this case, the evaluator might scrutinize the roster of unexposed children at a nearby school for the closest equivalent child to pair with each child participating in the program.

With aggregate matching, individuals are not matched case by case; rather, the overall distributions of values on the matching variables are made comparable for the intervention and control groups. For instance, a control group might be selected that has the same proportion of children by sex and age as the intervention group, but this may involve a 12-year-old girl and an 8-year-old boy in the control group to balance a 9-year-old girl and an 11-year-old boy in the intervention group. For both matching methods, the overall goal is to equally distribute characteristics that may impact the outcome variable. As a further safeguard, additional descriptive variables that have not been used for matching may be measured prior to intervention and incorporated in the analysis as statistical controls (discussed below).

The most common impact evaluation design is one in which the outcomes for an intervention group are compared with those of a control group selected on the basis of relevance and convenience. For a community-wide program for senior citizens, for instance, an evaluator might draw a control group from a similar community that does not have the program and is convenient to access. Because any estimate of program effects based on a simple comparison of outcomes for such groups must be presumed to include selection bias, this is a nonequivalent comparison group design.

Nonequivalent control (comparison) group designs are analyzed using statistical techniques that

attempt to control for the preexisting differences between groups. To apply statistical controls, the control variables must be measured on both the intervention and comparison groups before the intervention is administered. A significant limitation of both matched and nonequivalent comparison designs is that the evaluator generally does not know what differences there are between the groups nor which of those are related to the outcomes of interest.

With relevant control variables in hand, the evaluator must conduct a statistical analysis that accounts for their influence in a way that effectively and completely removes selection bias from the estimates of program effects. Typical approaches include **analysis of covariance** and **multiple linear regression** analysis. If all the relevant control variables are included in these analyses, the result should be an unbiased estimate of the intervention effect.

An alternate approach to dealing with nonequivalence that is becoming more commonplace is selection modeling. Selection modeling is a two-stage procedure in which the first step uses relevant control variables to construct a statistical model that predicts selection into the intervention or control group. This is typically done with a specialized form of regression analysis for binary dependent variables, for example, **probit** or **logistic regression**. The results of this first stage are then used to combine all the control variables into a single composite selection variable, or **propensity score** (propensity to be selected into one group or the other). The propensity score is optimized to account for the initial differences between the intervention and control groups and can be used as a kind of super control variable in an analysis of covariance or multiple regression analysis. Effective selection modeling depends on the evaluator's diligence in identifying and measuring variables related to the process by which individuals select themselves (e.g., by volunteering) or are selected (e.g., administratively) into the intervention or comparison group. Several variants of selection modeling and two-stage estimation of program effects are available. These include Heckman's econometric approach [6, 7], Rosenbaum and Rubin's propensity scores [14, 15], and **instrumental variables** [5].

The Magnitude of Program Effects

The ability of an impact evaluation to detect and describe program effects depends in large part on

the magnitude of those effects. Small effects are more difficult to detect than large ones and their practical significance may also be more difficult to describe. Evaluators often use an **effect size** statistic to express the magnitude of a program effect in a standardized form that makes it comparable across measures that use different units or different scales. The most common effect size statistic is the standardized mean difference (sometimes symbolized d), which represents a mean outcome difference between an intervention group and a control group in standard deviation units. Describing the size of a program effect in this manner indicates how large it is relative to the range of scores recorded in the study. If the mean reading readiness score for participants in a preschool intervention program is half a standard deviation larger than that of the control group, the standardized mean difference effect size is 0.50. The utility of this value is that it can be easily compared to, say, the standardized mean difference of 0.35 for a test of vocabulary. The comparison indicates that the preschool program was more effective in advancing reading readiness than in enhancing vocabulary.

Some outcomes are binary rather than a matter of degree; that is, for each participant, the outcome occurs or it does not. Examples of binary outcomes include committing a delinquent act, becoming pregnant, or graduating from high school. For binary outcomes, an **odds ratio** effect size is often used to characterize the magnitude of the program effect. An odds ratio indicates how much smaller or larger the odds of an outcome event are for the intervention group compared to the control group. For example, an odds ratio of 1.0 for high school graduation indicates even odds; that is, participants in the intervention group are no more and no less likely than controls to graduate. Odds ratios greater than 1.0 indicate that intervention group members are more likely to experience the outcome event; for instance, an odds ratio of 2.0 means that the odds of members of the intervention group graduating are twice as great as for members of the control group. Odds ratios smaller than 1.0 mean that they are less likely to graduate.

Effect size statistics are widely used in the **meta-analysis** of evaluation studies. Additional information can be found in basic meta-analysis texts such as those found in [4, 10, 16].

The Practical Significance of Program Effects

Effect size statistics are useful for summarizing and comparing research findings but they are not necessarily good guides to the practical magnitude of those effects. A small statistical effect may represent a program effect of considerable practical significance; conversely, a large statistical effect may be of little practical significance. For example, a very small reduction in the rate at which people with a particular illness are hospitalized may have important cost implications for health insurers. Statistically larger improvements in the patients' satisfaction with their care, on the other hand, may have negligible practical implications.

To appraise the practical magnitude of program effects, the statistical effect sizes must be translated into terms relevant to the social conditions the program aims to improve. For example, a common outcome measure for juvenile delinquency programs is the rate of rearrest within a given time period. If a program reduces rearrest rates by 24%, this amount can readily be interpreted in terms of the number of juveniles affected and the number of delinquent offenses prevented.

For other program effects, interpretation may not be so simple. Suppose that a math curriculum for low-performing sixth-grade students raised the mean score from 42 to 45 on the mathematics subtest of the Omnibus Test of Basic Skills, a statistical effect size of 0.30 standard deviation units. How much improvement in math skills does this represent in practical terms? Interpretation of statistical effects on outcome measures with values that are not inherently meaningful requires comparison with some external referent that puts the effect size in a practical context. With achievement tests, for instance, we might compare program effects against test norms. If the national norm on the math test is 50, the math curriculum reduced the gap between the students in the program and the norm by about 38% (from 8 points to 5), but still left them short of the average skill level.

Another referent for interpreting the practical magnitude of a program effect is a 'success' threshold on the outcome measure. A comparison of the proportions of individuals in the intervention and control groups who exceed the threshold reveals the practical magnitude of the program effect. For example, a mental health program that treats depression might

use the Beck Depression Inventory as an outcome measure. On this instrument, scores in the 17 to 20 range indicate borderline clinical depression, so one informative index of practical significance is the percent of patients with posttest scores less than 17. If 37% of the control group is below the clinical threshold at the end of the treatment period compared to 65% of the treatment group, the practical magnitude of this treatment effect can be more easily appraised than if the same difference is presented in arbitrary scale units.

Another basis of comparison for interpreting the practical significance of program effects is the distribution of effect sizes in evaluations of similar programs. For instance, a review of evaluation research on the effects of marriage counseling, or a meta-analysis of the effects of such programs, might show that the mean effect size for marital satisfaction was around 0.46, with most of the effect sizes ranging between 0.12 and 0.80. With this information, an evaluator who finds an effect size of 0.34 for a particular marriage-counseling program can recognize it as rather middling performance for a program of this type.

Statistical Power

Suppose that an evaluator has some idea of the magnitude of the effect that a program must produce to have a meaningful impact and can express it as an effect size statistic. An impact evaluation of that program should be designed so it can detect that effect size. The minimal standard for identifying an effect in a quantitative analysis is that it attains statistical significance. The probability that an estimate of the program effect based on sample data will be statistically significant when, in fact, it represents a real (population) effect of a given magnitude is called statistical **power**. Statistical power is a function of the effect size to be detected, the sample size, the type of statistical significance test used, and the alpha level.

Deciding the proper level of statistical power for an impact assessment is a substantive issue. If an evaluator expects that the program's statistical effects will be small and that such small effects are worthwhile, then a design powerful enough to detect them is needed. For example, the effect of an intervention that lowers automobile accident deaths by as little as 1% might be judged worth detecting

because saving lives is so important. In contrast, when an evaluator judges that an intervention is worthwhile only if its effects are large, a design that lacks power to detect small effects may be quite acceptable. Proficiency in statistical power estimation and its implications for sample size and statistical control variables is critical for competent impact evaluation. More detailed information can be found in [3, 9].

Moderator and Mediator Relationships

The experimental and quasi-experimental designs used for impact evaluation are oriented toward determining whether the program produces effects on specific outcome variables. They reveal little about how and when the program brings about its effects. For instance, program effects are rarely identical for all recipient subgroups and all circumstances of service delivery. Differences in outcomes related to the moderator variables (*see* **Moderation**) that describe these variations must be examined to identify the conditions under which the program is most and least effective. In addition, programs usually produce their effects through a causal chain in which they first affect proximal outcomes that, in turn, change other more distal outcomes. A mass media antidrug campaign, for instance, might attempt to change attitudes and knowledge about drug use with the expectation that such changes will lead to changes in drug-use behavior. Analysis of such intervening variables, or mediator relationships (*see* **Mediation**), helps explain the change mechanisms through which a program produces its effects.

To explore moderator relationships, evaluators examine statistical interactions between the potential moderator variables and the outcomes they may moderate. A simple case would be to divide the research sample into male and female subgroups, determine the mean program effect for each gender, and then compare those effects. If the effects are larger, say, for females than for males, it indicates that gender moderates the program effect. Demographic variables such as gender, age, ethnicity, and socioeconomic status often characterize groups that respond differently to a social program. Moreover, it is not unusual for different program sites, personnel configurations, and procedures to be associated with variations in program effects.

In addition to uncovering differential program effects, evaluators can use moderator analysis to test their expectations about what differential effects should occur. In this use of moderator analysis, the evaluator reasons that, if the program is operating as expected and having effects, these effects should be larger here and smaller there – for example, larger where the behavior targeted for change is most prevalent, where more or better service is delivered, for groups that should be naturally more responsive, and so forth. A moderator analysis that confirms these expectations provides evidence that helps confirm the existence of program effects. A moderator analysis that fails to confirm expectations serves as a caution that there may be influence on the effect estimates other than the program itself.

Testing for mediator relationships hypothesized in the program logic is another way of probing evaluation findings to determine if they are consistent with expectations of a successful program. For example, suppose that the intended outcome of a program, in which adult volunteers mentor at-risk youths, is reductions in the youths' delinquent behavior. The hypothesized causal pathway is that contact with mentors influences the youths to emulate the values of their mentors and use leisure time more constructively. This, in turn, is expected to lead to reduced contact with antisocial peers and, finally, to decreased delinquent behavior. In this hypothesized pathway, constructive use of leisure time is the major mediating variable between program exposure and contact with peers. Contact with peers, similarly, is presumed to mediate the relationship between leisure time use and decreased delinquency.

Statistical procedures for examining mediator relationships assess the relationship between the independent variable and the mediator, the independent variable and the dependent variable, and the mediator and the dependent variable. The critical test is whether the relationship between the independent and dependent variables shrinks toward zero when the mediator is controlled statistically. Mediator relationships are usually tested with **multiple linear regression** analyses; discussions of the statistical procedures for conducting these tests can be found in [1, 11].

More sophisticated analysis procedures available for moderator and mediator analysis include multi-level modeling (*see* **Hierarchical Models**) [13, 19] and **structural equation modeling** [8, 17]. Impact evaluation can be designed to include the variables

needed for such analysis, and these analysis techniques can be combined with those for analyzing experimental designs [12]. By providing the tools to examine how, when, and where program effects are produced, evaluators avoid 'black box' evaluations that determine only whether effects were produced.

Event History Analysis

Introduction

The purpose of event history analysis is to explain why certain individuals are at a higher risk of experiencing the event(s) of interest than others. This can be accomplished by using special types of methods which, depending on the field in which they are applied, are called *failure-time models*, lifetime models, survival models (see **Survival Analysis**), transition-rate models, response-time models, event history models, duration models, or hazard models. Examples of textbooks discussing this class of techniques are [1, 2, 5, 7, 8, 10], and [12]. Here, we will use the terms event history, survival, and hazard models interchangeably.

A hazard model is a regression model in which the ‘risk’ of experiencing an event at a certain time point is predicted with a set of covariates. Two special features distinguish hazard models from other types of regression models. The first is that they make it possible to deal with **censored observations** which contain only partial information on the timing of the event of interest. Another special feature is that covariates may change their value during the observation period. The possibility of including such time-varying covariates makes it possible to perform a truly dynamic analysis. Before discussing in more detail the most important types of hazard models, we will first introduce some basic concepts.

State, Event, Duration, and Risk Period

In order to understand the nature of event history data and the purpose of event history analysis, it is important to understand the following four elementary concepts: state, event, duration, and risk period. These concepts are illustrated below using an example from the analyses of marital histories.

The first step in the analysis of event histories is to define the *states* that one wishes to distinguish. States are the categories of the ‘dependent’ variable, the dynamics of which we want to explain. At every particular point in time, each person occupies exactly one state. In the analysis of marital histories, four states are generally distinguished: never married, married, divorced, and widow(er). The set of possible states is sometimes also called the *state space*.

An *event* is a transition from one state to another, that is, from an origin state to a destination state. In this context, a possible event is ‘first marriage’, which can be defined as the transition from the origin state, never married, to the destination state, married. Other possible events are: a divorce, becoming a widow(er), and a non-first marriage. It is important to note that the states that are distinguished determine the definition of possible events. If only the states married and not married were distinguished, none of the above-mentioned events could have been defined. In that case, the only events that could be defined would be marriage and marriage dissolution.

Another important concept is the *risk period*. Clearly, not all persons can experience each of the events under study at every point in time. To be able to experience a particular event, one must occupy the origin state defining the event, that is, one must be at risk of the event concerned. The period that someone is at risk of a particular event, or exposed to a particular risk, is called the *risk period*. For example, someone can only experience a divorce when he or she is married. Thus, only married persons are at risk of a divorce. Furthermore, the risk period(s) for a divorce are the period(s) that a subject is married. A strongly related concept is the *risk set*. The risk set at a particular point in time is formed by all subjects who are at risk of experiencing the event concerned at that point in time.

Using these concepts, event history analysis can be defined as the analysis of the *duration of the nonoccurrence of an event* during the risk period. When the event of interest is ‘first marriage’, the analysis concerns the duration of nonoccurrence of a first marriage, in other words, the time that individuals remained in the state of never being married. In practice, as will be demonstrated below, the dependent variable in event history models is not duration or time itself but a transition rate. Therefore, event history analysis can also be defined as the analysis of rates of occurrence of the event during the risk period. In the first marriage example, an event history model concerns a person’s marriage rate during the period that he/she is in the state of never having been married.

Basic Statistical Concepts

Suppose that we are interested in explaining individual differences in women’s timing of the first birth.

2 Event History Analysis

In that case, the event is having a first child, which can be defined as the transition from the origin state no children to the destination state one child. This is an example of what is called a *single nonrepeatable event*, where the term single reflects that the origin state no children can only be left by one type of event, and the term nonrepeatable indicates that the event can occur only once. For the moment, we concentrate on such single nonrepeatable events, but later on we show how to deal with multiple type and repeatable events.

The manner in which the basic statistical concepts of event history models are defined depends on whether the time variable T – indicating the duration of nonoccurrence of an event – is assumed to be continuous or discrete. Even though it seems in most applications it is most natural to treat T as a continuous variable, sometimes this assumption is not realistic. Often, T is not measured accurately enough to be treated as strictly continuous, for example, when the duration variable in a study on the timing of the first birth is measured in completed years instead of months or days. In other applications, the events of interest can only occur at particular points in time, such as in studies on voting behavior.

Here, we will assume that the T is a continuous random variable, for example, indicating the duration of nonoccurrence of the first birth. Let $f(t)$ be the probability density function of T , and $F(t)$ the distribution function of T . As always, the following relationships exist between these two quantities,

$$\begin{aligned} f(t) &= \lim_{\Delta t \rightarrow 0} \frac{P(t \leq T < t + \Delta t)}{\Delta t} = \frac{\partial F(t)}{\partial t}, \\ F(t) &= P(T \leq t) = \int_0^t f(u)du. \end{aligned} \quad (1)$$

The *survival probability* or survival function, indicating the probability of nonoccurrence of an event until time t , is defined as

$$S(t) = 1 - F(t) = P(T \geq t) = \int_t^\infty f(u)du. \quad (2)$$

Another important concept is the *hazard rate* or hazard function, $h(t)$, expressing the instantaneous risk of experiencing an event at $T = t$, given that the event did not occur before t . The hazard rate is

defined as

$$h(t) = \lim_{\Delta t \rightarrow 0} \frac{P(t \leq T < t + \Delta t | T \geq t)}{\Delta t} = \frac{f(t)}{S(t)}, \quad (3)$$

in which $P(t \leq T < t + \Delta t | T \geq t)$ indicates the probability that the event will occur during $[t \leq T < t + \Delta t]$, given that the event did not occur before t . The hazard rate is equal to the unconditional instantaneous probability of having an event at $T = t$, $f(t)$, divided by the probability of not having an event before $T = t$, $S(t)$. It should be noted that the hazard rate itself cannot be interpreted as a conditional probability. Although its value is always nonnegative, it can take on values larger than one. However, for small Δt , the quantity $h(t)\Delta t$ can be interpreted as the approximate conditional probability that the event will occur between t and $t + \Delta t$.

Above $h(t)$ was defined as a function of $f(t)$ and $S(t)$. It is also possible to express $S(t)$ and $f(t)$ in terms of $h(t)$; that is,

$$\begin{aligned} S(t) &= \exp\left(-\int_0^t h(u)du\right), \\ f(t) &= h(t)S(t) = h(t)\exp\left(-\int_0^t h(u)du\right). \end{aligned} \quad (4)$$

This shows that the functions $f(t)$, $F(t)$, $S(t)$, and $h(t)$ give mathematically equivalent specifications of the distribution of T .

Log-linear Models for the Hazard Rate

When working within a continuous-time framework, the most appropriate method for regressing the time variable T on a set of covariates is through the hazard rate. This makes it straightforward to assess the effects of time-varying covariates – including the time dependence itself and time-covariate interactions – and to deal with censored observations. Censoring is a form of missing data that is explained in more detail below.

Let $h(t|\mathbf{x}_i)$ be the hazard rate at $T = t$ for an individual with covariate vector $\mathbf{x}_i$. Since the hazard rate can take on values between 0 and infinity, most hazard models are based on a log transformation of the hazard rate, which yields a regression model of the form

$$\log h(t|\mathbf{x}_i) = \log h(t) + \sum_j \beta_j x_{ij}. \quad (5)$$

This hazard model is not only log-linear but also proportional. In proportional hazard models, the time dependence is multiplicative (additive after taking logs) and independent of an individual's covariate values. The following section shows how to specify nonproportional log-linear hazard models by including time-covariate interactions.

The various types of continuous-time log-linear hazard models are defined by the functional form that is chosen for the time dependence, that is, for the term $\log h(t)$. In Cox's semiparametric model [3], the time dependence is left unspecified. Exponential models assume the hazard rate to be constant over time, while piecewise exponential model assume the hazard rate to be a step function of T , that is, constant within time periods. Other examples of parametric log-linear hazard models are Weibull, Gompertz, and polynomial models.

As was demonstrated by several authors (for example, see [6] or [10]), log-linear hazard models can also be defined as log-linear Poisson models, which are also known as log-rate models. Assume that we have – besides the event history information – two categorical covariates denoted by A and B . In addition, assume that the time axis is divided into a limited number of time intervals in which the hazard rate is postulated to be constant. In the first-birth example, this could be one-year intervals. The discretized time variable is denoted by T . Let h_{abt} denote the constant hazard rate in the t th time interval for an individual with $A = a$ and $B = b$. To see the similarity with standard **log-linear models**, it should be noted that the hazard rate, sometimes referred to as occurrence-exposure rate, can also be defined as $h_{abt} = m_{abt}/E_{abt}$. Here, m_{abt} denoted the expected number of occurrences of the event of interest and E_{abt} the total exposure time in cell (a, b, t) .

Using the notation of hierarchical log-linear models the saturated model for the hazard rate h_{abt} can now be written as

$$\log h_{abt} = u + u_a^A + u_b^B + u_t^T + u_{ab}^{AB} + u_{at}^{AT} + u_{bt}^{BT} + u_{abt}^{ABT}, \quad (6)$$

in which the u terms are log-linear parameters which are constrained in the usual way, for instance, by means of **analysis of variance**-like restrictions. Note that this is a nonproportional model because of the presence of time-covariate interactions. Restricted variants of model described in (6) can be obtained by

omitting some of the higher-order interaction terms. For example,

$$\log h_{abt} = u + u_a^A + u_b^B + u_t^T \quad (7)$$

yields a model that is similar to the proportional log-linear hazard model described in (5). In addition, different types of hazard models can be obtained by the specification of the time dependence. Setting the u_t^T terms equal to zero yields an exponential model. Unrestricted u_t^T parameters yield a piecewise exponential model. Other parametric models can be approximated by defining the u_t^T terms to be some function of T . And finally, if there are as many time intervals as observed survival times and if the time dependence of the hazard rate is not restricted, one obtains a Cox regression model. Log-rate models can be estimated using standard programs for log-linear analysis or Poisson regression using E_{abt} as a weight or exposure vector (see [10] and generalized linear models).

Censoring

An issue that always receives a great amount of attention in discussions on event history analysis is censoring. An observation is called *censored* if it is known that it did not experience the event of interest during some time, but it is not known when it experienced the event. In fact, censoring is a specific type of missing data. In the first-birth example, a censored case could be a woman who is 30 years of age at the time of interview (and has no follow-up interview) and does not have children. For such a woman, it is known that she did not have a child until age 30, but it is not known whether or when she will have her first child. This is, actually, an example of what is called *right censoring*. Another type of censoring that is more difficult to deal with is left censoring. Left censoring means that we do not have information on the duration of nonoccurrence of the event before the start of the observation period.

As long as it can be assumed that the censoring mechanism is not related to the process under study, dealing with right censored observations in **maximum likelihood estimation** of the parameters of hazard models is straightforward. Let δ_i be a censoring indicator taking the value 0 if observation i is censored and 1 if it is not censored. The contribution of case i to the likelihood function that must be

maximized when there are censored observations is

$$\begin{aligned}\mathcal{L}_i &= h(t_i|\mathbf{x}_i)^{\delta_i} S(t_i|\mathbf{x}_i) \\ &= h(t_i|\mathbf{x}_i)^{\delta_i} \exp\left(-\int_0^{t_i} h(u|\mathbf{x}_i) du\right).\end{aligned}\quad (8)$$

As can be seen, the likelihood contribution of a censored case equals its survival probability $S(t_i|\mathbf{x}_i)$, and of a noncensored case the density $f(t_i|\mathbf{x}_i)$, which equals $h(t_i|\mathbf{x}_i)^{\delta_i} S(t_i|\mathbf{x}_i)$.

Time-varying Covariates

A strong point of hazard models is that one can use time-varying covariates. These are covariates that may change their value over time. Examples of interesting time-varying covariates in the first-birth example are a woman's marital and work status. It should be noted that, in fact, the time variable and interactions between time and time-constant covariates are time-varying covariates as well.

The saturated log-rate model described in (6), contains both time effects and time-covariate interaction terms. Inclusion of ordinary time-varying covariates does not change the structure of this hazard model. The only implication of, for instance, covariate B being time varying rather than time constant is that in the computation of the matrix with exposure times E_{abt} it has to taken into account that individuals can switch from one level of B to another.

Multiple Risks

Thus far, only hazard rate models for situations in which there is only one destination state were considered. In many applications it may, however, prove necessary to distinguish between different types of events or risks. In the analysis of the first-union formation, for instance, it may be relevant to make a distinction between marriage and cohabitation. In the analysis of death rates, one may want to distinguish different causes of death. And in the analysis of the length of employment spells, it may be of interest to make a distinction between the events voluntary job change, involuntary job change, redundancy, and leaving the labor force.

The standard method for dealing with situations where – as a result of the fact that there is more than one possible destination state – individuals may

experience different types of events is the use of a multiple-risk or competing-risk model. A multiple-risk variant of the hazard rate model described in (5) is

$$\log h_d(t|\mathbf{x}_i) = \log h_d(t) + \sum_j \beta_{jd} x_{ij}. \quad (9)$$

Here, the index d indicates the destination state or the type of event. As can be seen, the only thing that changes compared to the single type of event situation is that we have a separate set of time and covariate effects for each type of event.

Repeatable Events and Other Types of Multivariate Event Histories

Most events studied in social sciences are repeatable, and most event history data contains information on repeatable events for each individual. This is in contrast to biomedical research, where the event of greatest interest is death. Examples of repeatable events are job changes, having children, arrests, accidents, promotions, and residential moves.

Often events are not only repeatable but also of different types, that is, we have a multiple-state situation. When people can move through a sequence of states, events cannot only be characterized by their destination state, as in competing risks models, but they may also differ with respect to their origin state. An example is an individual's employment history: an individual can move through the states of employment, unemployment, and out of the labor force. In that case, six different kinds of transitions can be distinguished, which differ with regard to their origin and destination states. Of course, all types of transitions can occur more than once. Other examples are people's union histories with the states living with parents, living alone, unmarried cohabitation, and married cohabitation, or people's residential histories with different regions as states.

Hazard models for analyzing data on repeatable events and multiple-state data are special cases of the general family of multivariate hazard rate models. Another application of these multivariate hazard models is the simultaneous analysis of different life-course events. For instance, it can be of interest to investigate the relationships between women's reproductive, relational, and employment careers, not only by means of the inclusion of time-varying

covariates in the hazard model, but also by explicitly modeling their mutual interdependence.

Another application of multivariate hazard models is the analysis of dependent or clustered observations. Observations are clustered, or dependent, when there are observations from individuals belonging to the same group or when there are several similar observations per individual. Examples are the occupational careers of spouses, educational careers of brothers, child mortality of children in the same family, or in medical experiments, measures of the sense of sight of both eyes or measures of the presence of cancer cells in different parts of the body. In fact, data on repeatable events can also be classified under this type of multivariate event history data, since in that case there is more than one observation of the same type for each observational unit as well.

The hazard rate model can easily be generalized to situations in which there are several origin and destination states and in which there may be more than one event per observational unit. The only thing that changes is that we need indices for the origin state (o), the destination state (d), and the rank number of the event (m). A log-linear hazard rate model for such a situation is

$$\log h_{od}^m(t|\mathbf{x}_i) = \log h_{od}^m(t) + \sum_j \beta_{jod}^m x_{ij}. \quad (10)$$

The different types of multivariate event history data have in common that there are dependencies among the observed survival times. These dependencies may take several forms: the occurrence of one event may influence the occurrence of another event; events may be dependent as a result of common antecedents; and survival times may be correlated because they are the result of the same causal process, with the same antecedents and the same parameters determining the occurrence or nonoccurrence of an event. If these common risk factors are not

observed, the assumption of statistical independence of observation is violated. Hence, unobserved heterogeneity should be taken into account.

Unobserved Heterogeneity

In the context of the analysis of survival and event history data, the problem of unobserved heterogeneity, or the bias caused by not being able to include particular important explanatory variables in the regression model, has received a great deal of attention. This is not surprising because this phenomenon, which is also referred to as selectivity or frailty, may have a much larger impact in hazard models than in other types of regression models:

We will illustrate the effects of unobserved heterogeneity with a small example. Suppose that the population under study consists of two subgroups formed by the two levels of an observed covariate A , where for an average individual with $A = 2$ the hazard rate is twice as high as for someone with $A = 1$. In addition, assume that within each of the levels of A there is (unobserved) heterogeneity in the sense that there are two subgroups within levels of A denoted by $W = 1$ and $W = 2$, where $W = 2$ has a 5 times higher hazard rate than $W = 1$. Table 1 shows the assumed hazard rates for each of the possible combinations of A and W at four time points. As can be seen, the true hazard rates are constant over time within levels of A and W . The reported hazard rates in the columns labeled 'observed' show what happens if we cannot observe W . First, it can be seen that despite that the true rates are time constant, both for $A = 1$ and $A = 2$ the observed hazard rates decline over time. This is an illustration of the fact that unobserved heterogeneity biases the estimated time dependence in a negative direction. Second, while the ratio between the hazard rates for $A = 2$ and $A = 1$ equals the true value 2.00 at $t = 0$, the

Table 1 Hazard rates illustrating the effect of unobserved heterogeneity

Time point	$A = 1$			$A = 2$			Ratio between $A = 2$ and $A = 1$
	$W = 1$	$W = 2$	Observed	$W = 1$	$W = 2$	Observed	
0	.010	.050	.030	.020	.100	.060	2.00
10	.010	.050	.026	.020	.100	.045	1.73
20	.010	.050	.023	.020	.100	.034	1.50
30	.010	.050	.019	.020	.100	.027	1.39

observed ratio declines over time (see last column). Thus, when estimating a hazard model with these observed hazard rates, we will find a smaller effect of A than the true value of $(\log) 2.00$. Third, in order to fully describe the pattern of observed rates, we need to include a time-covariate interaction in the hazard model: the covariate effect changes (declines) over time or, equivalently, the (negative) time effect is smaller for $A = 1$ than for $A = 2$.

Unobserved heterogeneity may have different types of consequences in hazard modeling. The best-known phenomenon is the downwards bias of the duration dependence. In addition, it may bias covariate effects, time-covariate interactions, and effects of time-varying covariates. Other possible consequences are dependent censoring, dependent competing risks, and dependent observations. The common way to deal with unobserved heterogeneity is included random effects in the model of interest (for example, see [4] and [9]).

The random-effects approach is based on the introduction of a time-constant latent covariate in the hazard model. The latent variable is assumed to have a multiplicative and proportional effect on the hazard rate, that is,

$$\log h(t|\mathbf{x}_i, \theta_i) = \log h(t) + \sum_j \beta_j x_{ij} + \log \theta_i \quad (11)$$

Here, θ_i denotes the value of the **latent variable** for subject i . In the parametric random-effects approach, the latent variable is postulated to have a particular distributional form. The amount of unobserved heterogeneity is determined by the size of the standard deviation of this distribution: The larger the standard deviation of θ , the more unobserved heterogeneity there is.

Heckman and Singer [4] showed that the results obtained from a random-effects continuous-time hazard model can be sensitive to the choice of the functional form of the mixture distribution. They, therefore, proposed using a nonparametric characterization of the mixing distribution by means of a finite set of so-called mass points, or latent classes, whose number, locations, and weights are empirically determined (also, see [10]). This approach is implemented in the Latent GOLD software [11] for **latent class analysis**.

Example: First Interfirm Job Change

To illustrate the use of hazard models, we use a data set from the 1975 Social Stratification and Mobility Survey in Japan reported in Yamaguchi's [12] textbook on event history analysis. The event of interest is the first interfirm job separation experienced by the sample subjects. The time variable is measured in years. In the analysis, the last one-year time intervals are grouped together in the same way as Yamaguchi did, which results in 19 time intervals. It should be noted that contrary to Yamaguchi, we do not apply a special formula for the computation of the exposure times for the first time interval.

Besides the time variable denoted by T , there is information on the firm size (F). The first five categories range from small firm (1) to large firm (5). Level 6 indicates government employees. The most general log-rate model that will be used is of the form

$$\log h_{ft} = u + u_f^F + u_t^T. \quad (12)$$

The log-likelihood values, the number of parameters, as well as the BIC¹ values for the estimated models are reported in Table 2. Model 1 postulates that the hazard rate does neither depend on time or firm size and Model 2 is an exponential survival model with firm size as a nominal predictor. The large difference in the log-likelihood values of these two models shows that the effect of firm size on the rate of job change is significant. A Cox proportional hazard model is obtained by adding an unrestricted time effect (Model 3). This model performs much better than Model 2, which indicates that there is a strong time dependence. Inspection of the estimated time dependence of Model 3 shows that the hazard rate rises in the first time periods and subsequently starts decreasing slowly (see Figure 1). Models 4 and 5 were estimated to test whether it is possible to simplify the time dependence of the hazard rate on the basis of this information. Model 4 contains only time parameters for the first and second time point, which

Table 2 Test results for the job change example

Model	Log-likelihood	# parameters	BIC
1. $\{\}$	-3284	1	6576
2. $\{F\}$	-3205	6	6456
3. $\{Z, F\}$	-3024	24	6249
4. $\{Z_1, Z_2, F\}$	-3205	8	6471
5. $\{Z_1, Z_2, Z_{lin}, F\}$	-3053	9	6174

Figure 1 Time dependence according to model 3 and model 5

means that the hazard rate is assumed to be constant from time point 3 to 19. Model 5 is the same as Model 4 except for that it contains a linear term to describe the negative time dependence after the second time point. The comparison between Models 4 and 5 shows that this linear time dependence of the log hazard rate is extremely important: The log-likelihood increases 97 points using only one additional parameter. Comparison of Model 5 with the less restricted Model 3 and the more restricted Model 2 shows that Model 5 captures the most important part of the time dependence. Though according to the likelihood-ratio statistic the difference between Models 3 and 5 is significant, Model 5 is the preferred model according to the BIC criterion. Figure 1 shows how Model 5 smooths the time dependence compared to Model 3.

The log-linear hazard parameter estimates for firm size obtained with Model 5 are 0.51, 0.28, 0.03, -0.01, -0.48, and -0.34, respectively.² These show that there is a strong effect of firm size on the rate of a

first job change: The larger the firm the less likely an employee is to leave the firm or, in other words, the longer he will stay. Government employees (category 6) have a slightly higher (less low) hazard rate than employees of large firm (category 5).

Notes

1. BIC is defined as minus twice the log-likelihood plus $\ln(N)$ times the number of parameters, where N is the sample size (here 1782).
2. Very similar estimates are obtained with Model 3.

Exact Methods for Categorical Data

Introduction

The validity of methods based on *asymptotic theory* is doubtful when sample size is small, as well as when data are sparse, skewed, or heavily tied. One way to form valid statistical inferences under these adverse data conditions is to compute exact P values, based on the distribution of *all* possible values of a test statistic that could be obtained from a given set of data. *Exact tests* are procedures for determining statistical significance using the **sampling distribution** of the test statistic obtained from the observed data: instead of evaluating the data in reference to some underlying theoretical population distribution, the data itself are employed to construct the relevant sampling distribution. Probability values are considered ‘exact’ in exact tests, since the P values are obtained from a sampling distribution composed of all possible values of test statistic computable from the data.

Exact P values can be obtained for a large number of nonparametric (*see* **Distribution-free Inference, an Overview**) statistical tests, including simple linear rank statistics (*see* **Rank Based Inference**) based on Wilcoxon scores, median scores, Van der Waerden scores, and Savage scores. Exact P values can also be obtained for univariate (e.g., the independent means t Test) and multivariate (e.g., Hotelling’s T^2) normal statistical tests.

Creating the ‘Exact’ Sampling Distribution of a Test Statistic

The most important questions to be addressed are (a) how the sampling distribution of a test statistic is obtained from an observed data set, that is, how is each sample constructed, and (b) how many samples are required. Whatever the answer to (a), the number of samples drawn is exhaustive in exact tests. By ‘exhaustive’, we mean all samples that could possibly be constructed in a specified way are selected.

As an example, consider how an exact test of a single median is performed. In this situation, we are required to assign positive and negative signs in all

possible combinations to the data. Let us say our data are composed of four values: 2, 4, 6, and 8. Since there are four numbers, each of which could be positive or negative, there are $2^N = 2^4 = 16$ possible combinations:

- | | |
|-------------------|-------------------|
| 1. 2, 4, 6, 8 | 2. -2, 4, 6, 8 |
| 3. -2, -4, 6, 8 | 4. -2, -4, -6, 8 |
| 5. -2, -4, -6, -8 | 6. 2, -4, 6, 8 |
| 7. 2, -4, -6, 8 | 8. 2, -4, -6, -8 |
| 9. 2, -4, -6, 8 | 10. 2, 4, -6, -8 |
| 11. -2, 4, -6, 8 | 12. -2, 4, -6, -8 |
| 13. 2, 4, 6, -8 | 14. 2, 4, -6, -8 |
| 15. -2, 4, 6, -8 | 16. 2, -4, 6, -8 |

In this situation, the answer to (a) is, for each of the samples, to draw all the numbers from the data and assign each number a positive or negative sign. The answer to (a) also determines the answer to (b): according to the rule for the number of possible sequences of N observations, each of which may have K outcomes, K^N , there must be 16 unique sequences (samples) that could be drawn. From each of these 16 samples, a test statistic would be calculated, creating a sampling distribution of the statistic with 16 observations. (As explained below, the test statistic is the sum of the observations in a sample.)

In our next example, the number of unique ways that N observations can be distributed among K groups determines how many samples are to be drawn and is equal to

$$\frac{N!}{n_1!n_2!\dots n_K!}.$$

As an illustration, we wish to conduct a one-way **analysis of variance** (ANOVA) with three groups. Assume the following data were available:

- Group 1: 6, 8
 Group 2: 9, 11, 9
 Group 3: 17, 15, 16, 16

Therefore, group 1 has two observations ($n_1 = 2$), group 2 has three ($n_2 = 3$), and group 3 has four ($n_3 = 4$), for a total $N = 9$. The number of ways two, three, and four observations can be distributed across three groups is $9!/(2)!(3)!(4)! = 1260$.

Resampling Procedures

Differences among Permutation Tests, Randomization Tests, Exact Tests, and the Bootstrap

One should also note that a great deal of confusion exists for the terms *exact test*, permutation test (see **Permutation Based Inference**), and randomization test (see **Randomization Based Tests**) [7, 9, 13]. How do they differ? In general, no meaningful statistical differences exist among these tests; the few differences that exist are minor, and in most situations produce the same outcome. ‘Permutation test’ is the broadest and most commonly used term of three, generally referring to procedures that repeatedly sample, using various criteria depending on the method, by permutation, using some criterion. Exact tests are permutation tests. Randomization tests are specific types of permutation tests and are applied to the permutation of data from experiments in which subjects have been randomly assigned to treatment groups. Although the term ‘exact test’ is occasionally used instead of the more generic ‘permutation test’, to our knowledge, the only statistical procedure labeled as ‘exact’ is Fisher’s exact test. In the interest of semantic clarity, Fisher’s exact test should be labeled ‘Fisher’s permutation test’.

Permutation, randomization, and exact tests are types of *resampling procedures*, procedures that select samples of scores from the original data set. Good [10] provides a particularly comprehensive review of resampling procedures. A critical difference *does* exist between the three permutation-type tests and the **bootstrap**, a method of resampling to produce random samples of size n from an original data set of size N . The critical difference is that permutation tests are based on sampling without replacement while the bootstrap is based on sampling with replacement. Although both permutation-type tests and the bootstrap often produce similar results, the former appears to be more accurate for smaller samples [18].

Exact Test Examples

We illustrate exact tests with two examples.

The Pitman Test

The basic idea behind the **Pitman test** [15, 17] is that if a random sample is from a symmetric distribution

with an unknown median θ , then symmetry implies it is equally likely any sample value will differ from θ by some positive amount d , or by the same negative amount, $-d$, for all values of d . In the Pitman test, the null hypothesis could be that the population median θ is equal to a specific value θ_0 ($H_0: \theta = \theta_0$), whereas the two-sided alternative hypothesis is $H_1: \theta \neq \theta_0$. It is assumed that under H_0 , the sign of each of the N differences

$$d_i = x_i - \theta_0, \quad i = 1, 2, \dots, N \quad (1)$$

is equally likely to be positive or negative. Clearly, when H_0 is not correct, there is more likely to be preponderance either of positive or negative signs associated with the d_i .

Example

The final exam scores for nine students were 50, 80, 77, 95, 88, 62, 90, 91, and 74, with a median (θ) of 80. In the past, the median final exam score (θ_0) was 68. Thus, the teacher suspects that this class performed better than previous classes. In order to confirm this, the teacher tests the hypothesis that $H_0: \theta = 68$ against the alternative $H_1: \theta > 68$ using the Pitman test.

The only assumption required for the Pitman test is that under H_0 , deviations (d_i) from 68 should be symmetric. Consequently, if H_0 is correct, it follows that the sums of the positive and negative deviations from 68 should not differ. On the other hand, if H_1 is correct, the sum of the positive deviations should exceed the sum of the negative deviations; that is, the class as a whole performed better than a median score of 68 would suggest implying that this class did perform better than classes of previous years.

The first step in the Pitman test is to sum (S) the deviations actually observed in the data: the deviations are $d_1 = 50 - 68 = -18$, $d_2 = 80 - 68 = 12$, $d_3 = 77 - 68 = 9$, $\dots$, $d_9 = 74 - 68 = 6$, their sum $S = 95$. The next step results in a sampling distribution of the sum of deviations. Recall that under H_0 , there is an equal probability that any one of the deviations be positive or negative. The critical assumption in the Pitman test follows from the equal probability of positive and negative deviations: *Any combination of plus and minus signs attached to the nine deviations in the sample is equally likely.* Since there are nine deviations, and each of the

nine deviations can take on either one of two signs (+ or -), there are $2^9 = 512$ possible allocations of signs (two to each of nine differences). The idea behind the Pitman test is allocate signs to the deviations for all possible 512 allocations, and obtain the sum of the deviations for each allocation. The sampling distribution of the sum of the deviations under the null hypothesis is created from the resulting 512 sums. Using this distribution, we can determine what is the probability of obtaining a sum as great as or greater than the sum observed (i.e., $S = 95$) in the sample if the null hypothesis is correct. Our interest in the probability of a sum greater than 95 follows from the teacher's specification of a one-tailed H_1 : The teacher expects the current class's performance to be significantly better than in previous years; or to put it another way, the new median of 80 should be significantly greater than 65. If this probability is low enough, we reject the null hypothesis that the current class's median is 68.

For example, one of the 512 allocations of signs to the deviations gives each deviation a positive sign; that is, 35, 5, 8, 10, 3, 23, 5, 6, and 11. The sum of these deviations is 101. Conversely, another one of the 512 allocations gives each of the deviations a negative sign, resulting in a sum of -101. All 512 sums contribute to the sampling distribution of S . On the basis of this sampling distribution, the sum of 95 has a probability of .026 or less of occurring if the null hypothesis is correct. Given the low probability that H_0 is correct ($p < .026$, we reject H_0 and decide that the current class median of $80(\theta)$ is significantly greater the past median of $65(\theta_0)$. Maritz [13] and Sprent [17] provide detailed discussions of the Pitman test.

Fisher's Exact Test

Fisher's exact test provides an exact method for testing the null hypothesis of independence for categorical data in a 2×2 contingency table with both sets of marginal frequencies fixed in advance. The exact probability is calculated for a sample showing as much or more evidence for independence than that obtained. As with many exact tests, a number of samples are obtained from the data; in this case, all possible contingency tables having the

specified marginal frequencies. An empirical probability distribution is constructed that reflects the probability of observing each of the contingency tables. This test was first proposed in [8], [11], and [20], and is also known as the Fisher-Irwin test and as the Fisher-Yates test. It is discussed in many sources, including [2], [5], [6], [16], and [19].

Consider the following 2×2 contingency table.

$$\begin{array}{cc|c} & B_1 & B_2 & Totals \\ A_1 & a & b & a+b \\ A_2 & c & d & c+d \\ \hline & a+c & b+d & N \end{array}$$

The null hypothesis is that the categories of A and B are independent. Under this null hypothesis, the probability p of observing any particular table with all marginal frequencies fixed follows the hypergeometric distribution (see **Catalogue of Probability Density Functions**):

$$p = \frac{(a+c)!(b+d)!(a+b)!(c+d)!}{n!a!b!c!d!}. \quad (2)$$

This equation expresses the distribution of the four cell counts in terms of only one cell (it does not matter which). Since the marginal totals (i.e., $a+c$, $b+d$, $a+b$, $c+d$) are fixed, once the number of observations in one cell has been specified, the number of observations in the other three cells are not free to vary: the count for one cell determines the other three cell counts.

In order to test the null hypothesis of independence, a one-tailed P value can be evaluated as the probability of obtaining a result (a 2×2 contingency table with a particular distribution of observations) as extreme as the observed value in the one cell that is free to vary in one direction. That is, the probabilities obtained from the hypergeometric distribution in one tail are summed. Although in the following example the alternative hypothesis is directional, one can also perform a nondirectional Fisher exact test.

To illustrate Fisher's exact test, we analyze the results of an experiment examining the ability of a subject to discriminate correctly between two objects. The subject is told in advance exactly how many times each object will be presented and is required to make that number of identifications. This

4 Exact Methods for Categorical Data

is to ensure that the marginal frequencies remain fixed.

The results are given in the following contingency table.

	B_1	B_2	$Totals$
A_1	1	6	7
A_2	6	1	7
	7	7	14

Factor A represents the presentation of the two objects and factor B is the subject's identification of these. The null hypothesis is that the presentation of an object is independent of its identification; that is, the subject cannot correctly discriminate between the two objects.

Using the equation for the probability from a hypergeometric distribution, we obtain the probability of observing this table with its specific distribution of observations:

$$p = \frac{7!7!7!7!}{14!1!6!1!6!} = 0.014. \quad (3)$$

However, in order to evaluate the null hypothesis, in addition to the probability $p = 0.014$, we must also compute the probabilities for any sets of observed frequencies that are even more extreme than the observed frequencies. The only result that is more extreme is

	B_1	B_2	$Totals$
A_1	0	7	7
A_2	7	0	7
	7	7	14

The probability of observing this contingency table is

$$p = \frac{7!7!7!7!}{14!0!7!0!7!} = 0.0003. \quad (4)$$

When $p = 0.014$ and $p = 0.0003$ are added, the resulting probability of 0.0143 is the likelihood of obtaining a set of observed frequencies that is equal to or is more extreme than the set of observed frequencies by chance alone. If we use a one-tailed alpha of 0.05 as the criterion for rejecting the null hypothesis, the probability of 0.0143 suggests that the likelihood that the experimental results would occur by chance alone is too small. We therefore reject the null hypothesis: there is a relation between the presentation of the objects and the subject's correct identification of them –

the subject is able to discriminate between the two objects.

Prior to the widespread availability of computers, Fisher's exact was rarely performed for sample sizes larger than the one in our example. The reason for this neglect is attributable to the intimidating number of contingency tables that could possibly be observed with the marginal totals fixed to specific values and the necessity of computing a hypergeometric probability for each. If we arbitrarily choose cell a as the one cell of the four free to vary, the number of possible tables is $m_{\text{Low}} \leq a \leq m_{\text{High}}$, where $m_{\text{Low}} = \max(0, a + c + b + d - N)$ and $m_{\text{High}} = \min(a + c + 1, b + d + 1)$. Applied to our example, there $m_{\text{Low}} = \max(0, 0)$ and $m_{\text{High}} = \min(8, 8)$. Given $a = 1$, there is a range of $0 \leq 1 \leq 8$ possible contingency tables, each with a different distribution of observations. When the most 'extreme' distribution of observations results from an experiment, only one hypergeometric probability must be considered; as the results depart from 'extreme', additional hypergeometric probabilities must be calculated. All eight tables are given in Tables 1–8:

Table 1

	B_1	B_2	$Totals$
A_1	0	7	7
A_2	7	0	7
	7	7	14

$p = 0.0003$

Table 2

	B_1	B_2	$Totals$
A_1	1	6	7
A_2	6	1	7
	7	7	14

$p = 0.014$

Table 3

	B_1	B_2	$Totals$
A_1	2	5	7
A_2	5	2	7
	7	7	14

$p = 0.129$

Table 4

	B_1	B_2	$Totals$
A_1	3	4	7
A_2	4	3	7
	7	7	14

$p = 0.357$

Table 5

	B_1	B_2	$Totals$
A_1	4	4	7
A_2	3	3	7
	7	7	14

$p = 0.357$

Table 6

	B_1	B_2	$Totals$
A_1	5	2	7
A_2	2	5	7
	7	7	14

$p = 0.129$

Table 7

	B_1	B_2	$Totals$
A_1	6	1	7
A_2	1	6	7
	7	7	14

$p = 0.014$

Table 8

	B_1	B_2	$Totals$
A_1	7	0	7
A_2	0	7	7
	7	7	14

$p = 0.0003$

Note that the sum of the probabilities of the eight tables is ≈ 1.00 .

Several algorithms are available for computation of exact P values. A good review of these algorithms is given by Agresti [1]. Algorithms based on direct enumeration are very time consuming and feasible for only smaller data sets. The network algorithm,

authored by Mehta and Patel [14], is a popular and efficient alternative direct enumeration.

Fisher's exact test may also be applied to any $K \times J \times L$ or higher contingency table; in the specific case of $2 \times 2 \times K$ contingency tables, the test is more commonly referred to as the Cochran–Mantel–Haenszel test (see **Mantel–Haenszel Methods**) [3, 12]. Exact tests have also been developed for **contingency tables** having factors with ordered categories [4].

Expectancy Effect by Experimenters

Some expectation of how the research will turn out is virtually a constant in science. Social scientists, like other scientists generally, conduct research specifically to examine hypotheses or expectations about the nature of things. In the social and behavioral sciences, the hypothesis held by the investigators can lead them unintentionally to alter their behavior toward the research participants in such a way as to increase the likelihood that participants will respond so as to confirm the investigator's hypothesis or expectations. We are speaking, then, of the investigator's hypothesis as a self-fulfilling prophecy. One prophesies an event, and the expectation of the event then changes the behavior of the prophet in such a way as to make the prophesied event more likely. The history of science documents the occurrence of this phenomenon with the case of Clever Hans as a prime example [3].

The first experiments designed specifically to investigate the effects of experimenters' expectations on the results of their research employed human research participants. Graduate students and advanced undergraduates in the field of Psychology were employed to collect data from introductory psychology students. The experimenters showed a series of photographs of faces to research participants and asked participants to rate the degree of success or failure reflected in the photographs. Half the experimenters, chosen at random, were led to expect that their research participants would rate the photos as being of more successful people. The remaining half of the experimenters were given the opposite expectation – that their research participants would rate the photos as being of less successful people. Despite the fact that all experimenters were instructed to conduct a perfectly standard experiment, reading only the same printed instructions to all their participants, those experimenters who had been led to expect ratings of faces as being of more successful people obtained such ratings from their randomly assigned participants. Those experimenters who had been led to expect results in the opposite direction tended to obtain results in the opposite direction.

These results were replicated dozens of times employing other human research participants [7]. They were also replicated employing animal research

subjects. In the first of these experiments, experimenters who were employed were told that their laboratory was collaborating with another laboratory that had been developing genetic strains of maze-bright and maze-dull rats. The task was explained as simply observing and recording the maze-learning performance of the maze-bright and maze-dull rats. Half the experimenters were told that they had been assigned rats that were maze-bright while the remaining experimenters were told that they had been assigned rats that were maze-dull. None of the rats had really been bred for maze-brightness or maze-dullness, and experimenters were told purely at random what type of rats they had been assigned. Despite the

Table 1 Strategies for the control of experimenter expectancy effects

1. Increasing the number of experimenters:
 - decreases learning of influence techniques,
 - helps to maintain blindness,
 - minimizes effects of early data returns,
 - increases generality of results,
 - randomizes expectancies,
 - permits the method of collaborative disagreement, and
 - permits statistical correction of expectancy effects.
2. Observing the behavior of experimenters:
 - sometimes reduces expectancy effects,
 - permits correction for unprogrammed behavior, and
 - facilitates greater standardization of experimenter behavior.
3. Analyzing experiments for order effects:
 - permits inference about changes in experimenter behavior.
4. Analyzing experiments for computational errors:
 - permits inference about expectancy effects.
5. Developing selection procedures:
 - permits prediction of expectancy effects.
6. Developing training procedures:
 - permits prediction of expectancy effects.
7. Developing a new profession of psychological experimenter:
 - maximizes applicability of controls for expectancy effects, and
 - reduces motivational bases for expectancy effects.
8. Maintaining blind contact:
 - minimizes expectancy effects (see Table 2).
9. Minimizing experimenter-participant contact:
 - minimizes expectancy effects (see Table 2).
10. Employing expectancy control groups:
 - permits assessment of expectancy effects.

2 Expectancy Effect by Experimenters

fact that the only differences between the allegedly bright and dull rats were in the mind of the experimenter, those who believed their rats were brighter obtained brighter performance from their rats than did the experimenters who believed their rats were duller. Essentially the same results were obtained in a replication of this experiment employing Skinner boxes instead of mazes. Tables 1 and 2 give a brief overview of some of the procedures that have been proposed to help control the methodological problems created by experimenter expectancy effects [4].

The research literature of the experimenter expectancy effect falls at the intersection of two distinct domains of research. One of these domains is the domain of artifacts in behavioral research [4, 6, 8], including such experimenter-based artifacts

as observer error, interpreter error, intentional error, effects of biosocial and psychosocial attributes, and modeling effects; and such participant-based artifacts as the perceived **demand characteristics** of the experimental situation, **Hawthorne effects** and volunteer bias.

The other domain into which the experimenter expectancy effect simultaneously falls is the more substantive domain of interpersonal expectation effects. This domain includes the more general, social psychology of the interpersonal self-fulfilling prophecy. Examples of major subliterations of this domain include the work on managerial expectation effects in business and military contexts [2] and the effects of teachers' expectations on the intellectual performance of their students [1, 5].

Table 2 Blind and minimized contact as controls for expectancy effects

Blind contact	
A.	Sources of breakdown of blindness
1.	Principal investigator
2.	Participant ('side effects')
B.	Procedures facilitating maintenance of blindness
1.	The 'total-blind' procedure
2.	Avoiding feedback from the principal investigator
3.	Avoiding feedback from the participant
Minimized contact	
A.	Automated data collection systems
1.	Written instructions
2.	Tape-recorded instructions
3.	Filmed instructions
4.	Televised instructions
5.	Telephoned instructions
6.	Computer-based instructions
B.	Restricting unintended cues to participants and experimenters
1.	Interposing screen between participants and experimenters
2.	Contacting fewer participants per experimenter
3.	Having participants or computers record responses

Expectation

The expectation or expected value of a random variable is also referred to as its mean or ‘average value.’ The terms *expectation*, *expected value*, and *mean* can be used interchangeably. The expectation can be thought of as a measure of the ‘center’ or ‘location’ of the probability distribution of the random variable. Two other measures of the center or location are the median and the mode. If the random variable is denoted by the letter X , the expectation of X is usually denoted by $E(X)$, said ‘E of X .’

The form of the definition of the expectation of a random variable is slightly different depending on the nature of the probability distribution of the random variable (see **Catalogue of Probability Density Functions**). The expectation of a discrete random variable is defined as the sum of each value of the random variable weighted by the probability that the random variable is equal to that value. Thus,

$$E(X) = \sum_x x f(x), \quad (1)$$

where $f(x)$ denotes the probability distribution of the discrete random variable, X . So, for example, suppose that the random variable X takes on five discrete values, -2 , -1 , 0 , 1 , and 2 . It could be an item on a questionnaire, for instance. Also suppose that the probability that the random variable takes on the value -2 (i.e., $(X = -2)$) is equal to 0.1 , and that $P(X = -1) = 0.2$, $P(X = 0) = 0.3$, $P(X = 1) = 0.25$, and $P(X = 2) = 0.15$. Then,

$$E(X) = (-2 * 0.1) + (-1 * 0.2) + (0 * 0.3) + (1 * 0.25) + (2 * 0.15) = 0.15. \quad (2)$$

Note that the individual probabilities sum to 1. The expectation is meant to summarize a ‘typical’ observation of the random variable but, as can be seen from the example above, the expectation of a random variable is not necessarily equal to one of the values of that random variable. It can also be very sensitive to small changes in the probability assigned to a large value of X .

It is possible that the expectation of a random variable does not exist. In the case of a discrete random variable, this occurs when the sum defining the expectation does not converge or is not equal to infinity.

Consider the *St. Petersburg paradox* discovered by the Swiss eighteenth-century mathematician Daniel Bernoulli (see **Bernoulli Family**) [1]. A fair coin is tossed repeatedly until it shows tails. The total number of tosses determines the prize, which equals $\$2^n$, where n is the number of tosses. The expected value of the prize for each toss is $\$1$ ($2 * 0.5 + 0 * 0.5$). The expected value of the prize for the game is the sum of the expected values for each toss. As there are an infinite number of tosses, the expected value of the prize for the game is an infinite number of dollars.

The expectation of a continuous random variable is defined as the integral of the individual values of the random variable weighted according to their probability distribution. Thus,

$$E(X) = \int_{-\infty}^{\infty} x f(x) dx, \quad (3)$$

where $f(x)$ is the probability distribution of the continuous random variable, X . This achieves the same end for a continuous random variable as (1) did for a discrete random variable; it sums each value of the random variable weighted by the probability that the random variable is equal to that value.

Again it is possible that the expectation of the continuous random variable does not exist. This occurs when the integral does not converge or equals infinity. A classic example of a random variable whose expected value does not exist is a Cauchy random variable.

An expectation can also be calculated for the function of a random variable. This is done by applying (1) or (3) to the distribution of a function of the random variable. For example, a function of the random variable X is $(X - \mu_X)^2$, where μ_X denotes the mean of the random variable X . The expectation of this function is referred to as the variance of X .

Expectations have a number of useful properties.

1. The expectation of a constant is equal to that constant.
2. The expectation of a constant multiplied by a random variable is equal to the constant multiplied by the expectation of the random variable.
3. The expectation of the sum of a group of random variables is equal to the sum of their individual expectations.
4. The expectation of the product of a group of random variables is equal to the product of their

2 Expectation

individual expectations if the random variables are independent.

More information on the topic of expectation is given in [2], [3] and [4].

Experimental Design

Experiments are, as **Sir Ronald Fisher** remarked, ‘only experience carefully planned in advance and designed to form a secure basis of new knowledge’ [3, p. 8]. The goal of experimental design is to allow inferences to be drawn that are logically compelled by the data about the effects of treatments. Efficiency and generalizability are also important concerns, but are logically secondary to the interpretability of the experiment.

The primary goal of experimental design is assessing causal relationships. This is a different focus from those methodologies, central to epidemiology or sociology, that attempt to determine the prevalence of a phenomenon in a population. When one wants to determine the prevalence of a disease or a political opinion, for example, the primary concern must be with the representativeness of the sample, and hence *random sampling* and the accompanying statistical theory regarding various sampling procedures are critical concerns (see **Randomization**) [1]. In experimental design, however, the methodological feature regarded, at least since the time of Fisher, as most critical is *random assignment* to conditions. Random assignment assures that no uncontrolled factor will, in the long run, bias the comparison of conditions, and hence provides the secure basis for causal inferences that Fisher was seeking. The use of random assignment also provides the justification for using mathematical models involving random processes and for making probabilistic statements that guide the interpretation of the experiment, as seen most explicitly in what are called **randomization tests** or **permutation tests** [2, 4].

When random assignment is not feasible, one of a variety of **quasi-experimental** or nonrandomized designs can be employed (see **observational studies**) [6], though threats to the validity of inferences abound in such studies. For example, in a design with nonequivalent groups, any differences on a posttest may be due to preexisting differences or selection effects rather than the treatment. Biases induced by nonrandom assignment may be exacerbated when participants self-select into conditions, whereas group similarity can sometimes be increased by matching. While attempts to control for **confounding variables** via matching or **analysis of covariance** are of some value, one cannot be assured that all the relevant

differences will be taken into account or that those that one has attempted to adjust for have been perfectly measured [5].

In the behavioral sciences, dependent variables usually are reasonably continuous. Experimenters typically attempt to account for or predict the variability of the dependent variables by factors that they have manipulated, such as group assignment, and by factors that they have measured, such as a participant’s level of depression prior to the study. Manipulated factors are almost always discrete variables, whereas those that are measured, although sometimes discrete, are more often continuous. To account for variability in the dependent variable, the most important factors to include in a statistical model are usually continuous measures of preexisting individual differences among participants (see **Nuisance Variables**). However, such ‘effects’ may not be causal, whereas the effects of manipulated factors, though perhaps smaller, will have a clearer theoretical interpretation and practical application. This is especially true when the participants are randomly assigned to levels of those factors.

Randomized designs differ in a variety of ways: (a) the number of factors investigated, (b) the number of levels of each factor and how those levels are selected, (c) how the levels of different factors are combined, and (d) whether the participants in the study experience only one treatment or more than one treatment (see **Analysis of Variance: Classification**). The simplest experimental designs have only a single factor. In the most extreme case, a single group of participants may experience an experimental treatment, but there is no similar control group. This design constitutes a *one-shot case study* [6], and permits only limited testing of hypotheses. If normative data on a psychological measure of depression are available, for example, one can compare posttreatment scores on depression for a single group to those norms. However, discrepancies from the norms could be caused either by the treatment or by differences between the individuals in the study and the characteristics of the participants in the norm group. A preferable design includes one or more control groups whose performance can be compared with that of the group of interest. When more than two groups are involved, one will typically be interested not only in whether there are any differences among the groups, but also in specific comparisons among combinations

2 Experimental Design

of group means. Designs in which the groups experience different levels of a single factor are referred to as *one-way designs*, because the groups differ in one way or along one dimension.

For practical or theoretical reasons, an experimenter may prefer to include multiple factors in a single study rather than performing a separate experiment to investigate each factor. An added factor could represent some characteristic of the participants such as gender. Including gender as a second factor along with the factor of treatment condition typically increases the power of the *F* test to detect the effect of the treatment factor as well as allowing a check on the consistency of the effect of that factor across male and female subgroups. When the various conditions included in a study represent combinations of levels of two different factors, the design is referred to as a *two-way* or **factorial design**. One-way designs can be represented with a schematic involving a group of a cells differing along one dimension. In the usual case, two-way designs can be represented as a two-dimensional table.

Experimental designs with multiple factors differ in which combinations of levels of the different factors are utilized. In most cases, all possible combinations of levels of the factors occur. The factors in such a design are said to be *crossed*, with all levels of one factor occurring in conjunction with every level of the other factor or factors. Thus, if there are *a* levels of Factor A and *b* levels of Factor B, there are *a* × *b* combinations of levels in the design. Each combination of levels corresponds to a different cell of the rectangular schematic of the design. Alternatively, a design may not include all of the possible combinations of levels. The most common example of such an incomplete design is one where nonoverlapping subsets of levels of one factor occur in conjunction with the different levels of the other factor. For example, in a comparison of psychoanalytic and cognitive behavioral therapies, the therapists may be qualified to deliver one method but not the other method. In such a case, the therapists would be *nested* within therapy methods. In contrast, if all therapists used both methods, therapists would be crossed with methods. Diagrams of these designs are shown in Figure 1.

Experimental designs also differ in terms of the way the levels of a particular factor are selected for inclusion in the experiment. In most instances, the levels are included because of an inherent interest in

Crossed design

	Psychoanalytic	Cognitive behavioral
Therapist 1		
Therapist 2		
Therapist 3		
Therapist 4		
Therapist 5		
Therapist 6		

Nested design

	Psychoanalytic	Cognitive behavioral
Therapist 1		missing
Therapist 2		missing
Therapist 3		missing
Therapist 4	missing	
Therapist 5	missing	
Therapist 6	missing	

Figure 1 Diagrams of crossed and nested designs

the specific levels. One might be interested in particular drug treatments or particular patient groups. In any replication of the experiment, the same treatments or groups would be included. Such factors are said to be *fixed* (see **Fisherian Tradition in Behavioral Genetics** and **Fixed and Random Effects**). Any generalization to other levels or conditions besides those included in the study must be made on nonstatistical grounds. Alternatively, a researcher can select the levels of a factor for inclusion in a study at random from some larger set of levels. Such factors are said to be random, and the random selection procedure permits a statistical argument to be made supporting the generalization of findings to the larger set of levels. The nature of the factors, fixed versus random, affects the way the statistical analysis of the data is carried out as well as the interpretation of the results.

Perhaps the most important distinction among experimental designs is whether the designs are *between-subjects* designs or *within-subjects* designs. The distinction is based on whether each subject experiences only one experimental condition or multiple experimental conditions. The advantage of between-subjects designs is that one does not need to be concerned about possible **carryover effects** from other conditions because the subject experiences only one condition. On the other hand, a researcher may want to use the same participants under different

conditions. For example, each participant can be used as his or her own control by contrasting that participant's performance under one condition with his or her performance under another condition. In many cases in psychology, the various conditions experienced by a given participant will correspond to observations at different points in time. For example, a test of clinical treatments may assess clients at each of several follow-up times. In this case, the same participants are observed multiple times. While there are obvious advantages to this procedure in terms of efficiency, conventional **analysis-of-variance** approaches to within-subjects designs (see **Repeated Measures Analysis of Variance** and **Educational Psychology: Measuring Change Over Time**) require that additional assumptions be made about the data. These assumptions are often violated. Furthermore, within-subjects designs require that participants have no **missing data** [5]. A variety of methods for dealing with these issues have been developed in recent years, including

various imputation methods and hierarchical linear modeling procedures.

Exploratory Data Analysis

For most statisticians in the late 1960s and early 1970s, the really hot topics in their subject were definitely not simple descriptive statistics or basic plots. Instead, the fireworks came from the continuing debates over the nature of statistical inference and the foundations of probability, followed closely by the modeling of increasingly complex experimental designs within a general **analysis of variance** setting, an area that was boosted by the growing availability of cheap and powerful computing facilities. However, in an operation reminiscent of the *samizdat* in the latter days of the Soviet Union (which secretly circulated the banned novels of Aleksandr Solzhenitsyn, amongst other things), mimeographed copies of a revolutionary recasting of statistics began their hand-to-hand journey around a selected number of universities from early 1970 onwards.

This heavily thumbed, three-volume text was not the work of a dissident junior researcher impatient with the conservatism of their elders, but was by one of America's most distinguished mathematicians, **John Tukey**. What Tukey did was to reestablish the relationship between these neglected descriptive measures (and plots) and many of the currently active areas in statistics, including computing, modeling, and inference. In doing so, he also resuscitated interest in the development of new summary measures and displays, and in the almost moribund topic of regression. The central notion behind what he termed *Exploratory Data Analysis*, or EDA, is simple but fruitful: knowledge about the world comes from many wells and by many routes. One legitimate and productive way is to treat data not as merely supportive of already existing knowledge, but primarily as a source of new ideas and hypotheses. For Tukey, like a detective looking for the criminal, the world is full of potentially valuable material that could yield new insights into what might be the case. EDA is the active reworking of this material with the aim of extracting new meanings from it: 'The greatest value of a picture is when it *forces* us to notice what we never expected to see' [9, p. vi]. In addition, while EDA has very little to say about how data might be gathered (although there is a subdivision of the movement whose concentration on model evaluation could be said to have *indirect* implications for data collection), the movement is very concerned that the

tools to extract meaning from data do so with minimum ambiguity. What this indicates, using a slightly more technical term, is that EDA is concerned with *robustness*, that is, with the study of all the factors that disturb or distort conclusions drawn from data, and how to draw their teeth (see also [11] for an introduction to EDA, which nicely mixes the elementary with the sophisticated aspects of the topic).

A simple example here is the use of the median versus the arithmetic mean as a measure of *location*, where the former is said to be robust resistant to discrepant values or **outliers** because it is based only on the *position* of the middle number in the (ordered) sample, while the latter uses all the numbers and their values, however unrepresentative, in its calculation (see [5] for an introduction to outliers and their treatment and [7] for an account of outliers as collective social phenomena). Further, a **trimmed mean**, calculated from an *ordered* sample where, say, 10% of the top and bottom numbers have been removed, is also more robust resistant than the raw arithmetic mean based on all the readings, since trimming automatically removes any outliers, which, by definition, lie in the upper and lower tails of such a sample, and are few in number. In general, robust resistant measures are preferable to nonrobust ones because, while both give pretty much the same answer in samples where there are no outliers, the former yields a less distorted measure in samples where outliers are present. Tukey and some of his colleagues [1] set themselves the task of investigating over 35 separate measures of location for their robustness. Although the median and the percentage trimmed mean came out well, Tukey also promoted the computer-dependent *biweight* as his preferred measure of location. Comparable arguments can also be made for choosing a robust measure of *spread* (or *scale*) over a nonrobust one, with the *midspread*, that is, the middle 50% of a sample (or the difference between the upper and lower quartiles or *hinges*, to use Tukey's term), being more acceptable than the variance or the standard deviation. Since the experienced data explorer is unlikely to know beforehand what to expect with a given *batch* (Tukey's neologism for a *sample*), descriptive tools that are able to cope with messy data sets are preferable to the usual, but more outlier-prone, alternatives.

Plots that use robust rather than outlier-sensitive measures were also part of the EDA doctrine, thus the

ubiquitous **box and whisker plot** is based on both the median and the midspread, while the latter measure helps determine the whisker length, which can then be useful in identifying potential outliers. Similar novelties such as the **stem and leaf plot** are also designed for the median rather than the mean to be read off easily, as can the upper and lower quartiles, and hence the midspread. Rather more exotic birds such as *hanging or suspended rootograms* and *half normal plots* (all used for checking the Gaussian nature of the data) were either Tukey's own creation or that of workers influenced by him, for instance, Daniel and Wood [2], whose classic study of data modeling owed much to EDA. Tukey did not neglect earlier and simpler displays such as **scatterplots**, although, true to his radical program, these became transformed into windows onto data shape and symmetry, robustness, and even robust differences of location and spread. A subset of these displays, **residual** and **leverage plots**, for instance, also played a key role in the revival of interest in regression, particularly in the area termed *regression diagnostics* (see [6]). In addition, while EDA has concentrated on relatively simple data sets and data structures, there are less well known but still provocative incursions into the partitioning of multiway and multifactor tables [3], including Tukey's rethinking of the analysis of variance (see [4]).

While EDA offered a flexibility and adaptability to knowledge-building missing from the more formal processes of statistical inference, this was achieved with a loss of certainty about the knowledge gained – provided, of course, that one believes that more formal methods do generate truth, or your money back. Tukey was less sure on this latter point in that while formal methods of inference are bolted onto EDA in the form of Confirmatory Data Analysis, or CDA (which favored the Bayesian route – see Mosteller and Tukey's early account of EDA and CDA in [8]), he never expended as much effort on CDA as he did on EDA, although he often argued that both should run in harness, with the one complementing the other. Thus, for Tukey (and EDA), truth gained by such an epistemologically *inductive* method was always going to be partial, local and relative, and liable to fundamental challenge and change. On the other hand, without taking such risks, nothing new could emerge. What seemed to be on offer, therefore, was an *entrepreneurial* view of statistics, and *science*, as permanent revolution.

Although EDA broke cover over twenty-five years ago with the simultaneous publication of the two texts on EDA and regression [10, 9], it is still too early to say what has been the real impact of EDA on data analysis. On the one hand, many of EDA's graphical novelties have been incorporated into most modern texts and computer programs in statistics, as have the raft of robust measures on offer. On the other, the risky approach to statistics adopted by EDA has been less popular, with deduction-based inference taken to be the only way to discover the world. However, while one could point to underlying and often contradictory cultural movements in scientific belief and practice to account for the less than wholehearted embrace of Tukey's ideas, the future of statistics lies with EDA.

External Validity

Cook and Campbell [2] identified many threats to our ability to generalize from an experiment to the larger population of people, settings, and methods. They distinguished between construct validity, which refers to the generalizability from the measures of an experiment to the constructs that were under investigation, and external validity, which refers to the degree to which any causal relationship that is found between an independent and a dependent variable can be generalized across people, settings, and times. For example, we often wonder whether the results we obtain in a tightly controlled social psychology experiment, with people communicating over an intercom rather than in person, would generalize to the 'real world'. In this case, we are talking about external validity.

Whereas **internal validity** refers to the degree to which any effect that is found for an experiment can be attributed to the causal action of the manipulated independent variable, external validity deals with generalizability. Campbell and Stanley considered internal validity to be the *sine qua non* of good experimental design. Without internal validity, it is not worth worrying about external validity. But without external validity, the interpretation of our results is severely limited, and perhaps meaningless for most practical situations.

Campbell and Stanley [1] were some of the first to discuss threats to external validity. This work was expanded by Cook and Campbell [2] in 1979, and, most recently, by Shadish, Cook, and Campbell [3] in 2002. This entry discusses five threats to external validity.

Threats to External Validity

- Interaction of selection and treatment
 - It is not uncommon to find that those who agree to participate in a particular experimental treatment differ from those who will not participate or drop out before the end of treatment. If this is the case, the results of those in the treatment condition may not generalize to the population of interest. Suppose,

for example, that we have a fairly unpleasant, though potentially effective, treatment for alcoholism. We create a treatment and a control condition by random assignment to conditions. Because the treatment is unpleasant, we have a substantial dropout rate in the treatment condition. Thus, at the end of the experiment, only the very highly motivated participants remain in that condition. In this case, the results, though perhaps internally valid, are unlikely to generalize to the population we wish to address all adults with alcohol problems. The treatment may be very good for the highly motivated, but it will not work for the poorly motivated because they will not stay with it.

- A similar kind of problem arises with special populations. For example, an experimental manipulation that has a particular effect on the ubiquitous 'college sophomore' may not apply, or may apply differently, to other populations. To show that a 'token economy' treatment works with college students does not necessarily mean that it will work with prison populations, to whom we might like to generalize.
- Interaction of setting and treatment
 - This threat refers to the fact that results obtained in one setting may not generalize to other settings. For example, when I was in graduate school in the mid-1960s, we conducted a verbal learning study on recruits on an air force base. The study was particularly boring for participants, but when their sergeant told them to participate, they participated! I have since wondered whether I would have obtained similar data if participation, using the same population of military personnel, was completely voluntary.
- Interaction of treatment effects with outcome measures
 - In the social sciences, we have a wealth of dependent variables to choose from, and we often choose the one that is the easiest to collect. For example, training programs for adolescents with behavior problems often target school attendance because that variable is easily obtained from school records. Intervention programs can be devised to improve

2 External Validity

attendance, but that does not necessarily mean that they improve the student's behavior in school, whether the student pays attention in class, whether the student masters the material, and so on. When we cannot generalize from one reasonable and desirable outcome variable to another, we compromise the external validity of the study.

- Interaction of treatment outcome with treatment variation
 - Often, the independent variable that we would like to study in an experiment is not easy to clearly define, and we select what we hope is an intelligent operationalization of that variable. (For example, we might wish to show that increasing the attention an adolescent receives from his or her peers will modify an undesirable behavior. However, you just need to think of the numerous ways we can 'pay attention' to someone to understand the problem.) Similarly an experimental study might use a multifaceted treatment, but when others in the future attempt to apply that in their particular setting, they may find that they only have the resources to implement some of the facets of the treatment. In these cases, the external validity of the study involving its ability to generalize to other settings, may be compromised.
 - Context-dependent mediation
 - Many causal relationships between an independent and a dependent variable are mediated by the presence or absence of another variable. For example, the degree to which your parents allowed you autonomy when you were growing up might affect your level of self-confidence, and that self-confidence might in turn influence the way you bring up your own children. In this situation, self-confidence is a mediating variable. The danger in generalizing from one experimental context to another involves the possibility that the mediating variable does not have the same influence in all contexts. For example, it is easy to believe that the mediating role of self-confidence may be quite different in children brought up under conditions of severe economic deprivation than in children brought up in a middle-class family.
- Other writers have proposed additional threats to external validity, and these are listed below. In general, any factors that can compromise our ability to generalize from the results of an experimental manipulation are threats to external validity.
- Interaction of history and treatment
 - Occasionally, the events taking place outside of the experiment influence the results. For example, experiments that happened to be conducted on September 11, 2001 may very well have results that differ from the results expected on any other day. Similarly, a study of the effects of airport noise may be affected by whether that issue has recently been widely discussed in the daily press.
 - Pretest-treatment interaction
 - Many experiments are designed with a pretest, an intervention, and a posttest. In some situations, it is reasonable to expect that the pretest will sensitize participants to the experimental treatment or cause them to behave in a particular way (perhaps giving them practice on items to be included in the posttest.). In this case, we would have difficulty generalizing to those who received the intervention but had not had a pretest.
 - Multiple-treatment interference
 - Some experiments are designed to have participants experience more than one treatment (hopefully in random order). In this situation, the response to one treatment may depend on the other treatments the individual has experienced, thus limiting generalizability.
 - Specificity of variables
 - Unless variables are clearly described and operationalized, it may be difficult to replicate the setting and procedures in a subsequent implementation of the intervention. This is one reason why good clinical psychological research often involves a very complete manual on the implementation of the intervention.
 - Experimenter bias
 - This threat is a threat to both **internal validity** and external validity. If even good experimenters have a tendency to see what they

expect to see, the results that they find in one setting, with one set of expectations, may not generalize to other settings.

- Reactivity effects
 - A classic study covered in almost any course on experimental design involves what is known as the **Hawthorne effect**. This is often taken to refer to the fact that even knowing that you are participating in an experiment may alter your performance. **Reactivity** effects refer to the fact that participants often ‘react’ to the very existence of an experiment in ways that they would not otherwise react.

For other threats to invalidity, see the discussion in the entry on **internal validity**. For approaches to

dealing with these threats, see **Nonequivalent Group Design**, **Regression Discontinuity Design**, and, particularly, **Quasi-experimental Designs**.

Face-to-Face Surveys

A face-to-face survey is a **telephone survey** without the telephone. The interviewer physically travels to the respondent's location to conduct a personal interview. Unlike the freewheeling type of interview one sees on *60 Minutes*, where the interviewer adapts the questions on the fly based on previous responses (or lack thereof), face-to-face surveys follow a standardized script without deviation, just like a mail or telephone survey. From the respondent's point of view, the process could not be easier: the interviewer arrives at a convenient, prearranged time, reads the survey for you, deals with any questions or problems that arise, records your answers, and is shown the door. No one calls you during supper and there are no envelopes to lick. This ease of response in fact makes face-to-face surveys ideally suited for populations that have difficulty answering mail or telephone surveys due to poor reading or writing skills, disability, or infirmity.

Compared with mail and telephone surveys, face-to-face surveys offer significant advantages in terms of the amount and complexity of the data that can be collected. For example, face-to-face surveys can be significantly longer. Most people will allow an interviewer to occupy their living room couch for up to an hour, whereas respondents will typically not tolerate telephone interviews that extend much beyond half an hour or mail surveys that require more than 15 or 20 min of effort. The additional length allows researchers the opportunity to ask more questions, longer questions, more detailed questions, more open-ended questions, and more complicated or technical questions. Skip patterns, in which different respondents navigate different paths through the survey depending on their answers, also can be more complicated. In addition, the use of graphic or visual aids, impossible by telephone and costly by mail, can be easily and economically incorporated into face-to-face surveys.

Face-to-face surveys also offer advantages in terms of data quality. More than any other survey delivery mode, a face-to-face survey allows researchers a high degree of control over the data collection process and environment. Interviewers can ensure, for example, that respondents do not skip ahead or 'phone a friend', as they might do when filling out a mail survey, or that they do not watch

TV or surf the internet during the interview, as they might do during a telephone survey. Since the interviewer elicits and records the data, the problems of missing data, ambiguous markings, and illegible handwriting that plague mail surveys are eliminated. If the respondent finds a question to be confusing or ambiguous, the interviewer can immediately clarify it. Similarly, the respondent can be asked to clarify any answers that the interviewer cannot interpret.

Perhaps the most important procedural variable affecting data quality in a survey study is the response rate, that is, the number of completed questionnaires obtained divided by the number of people who were asked to complete them. Since it is much more difficult for people to shut the door in the face of a live human being than hang up on a disembodied voice or toss a written survey into the recycling bin with the junk mail, face-to-face surveys typically offer the highest response rates obtainable (over 90% in some cases). Like telephone surveys, face-to-face surveys also avoid a type of response bias typical of mail surveys, namely, the tendency for respondents, on average, to be more highly educated than those who fail to respond.

Of course, all of these benefits typically come at a great cost to the researchers, who must carefully hire, train, and monitor the interviewers and pay them to travel from one neighborhood to the next (and sometimes back again) knocking on doors. Largely due to the nature and cost of the travel involved, face-to-face surveys can end up costing more than twice as much and taking more than three times as long to complete as an equivalent telephone survey. Face-to-face surveys can also have additional disadvantages. For example, budgetary constraints typically limit them to a comparatively small geographical area. Also, some populations can be difficult to reach in person because they are rarely at home (e.g., college students), access to their home or apartment is restricted, or traveling in their neighborhood places interviewers at risk. There is also evidence that questions of a personal nature are less likely to be answered fully and honestly in a face-to-face survey. This is probably because respondents lose the feeling of anonymity that is easily maintained when the researcher is safely ensconced in an office building miles away. In addition, because face-to-face interviews put people on the spot by requiring an immediate answer, questions that require a lot

2 Face-to-Face Surveys

of reflection or a search for personal records are better handled by the self-paced format of a mail survey.

Perhaps the largest 'cost' associated with a face-to-face survey is the increased burden placed on the researcher to ensure that the interviewers who are collecting the data do not introduce 'interviewer bias', that is, do not, through their words or actions, unintentionally influence respondents to answer in a particular way. While interviewer bias is also a concern in telephone surveys, it poses even more of a problem in face-to-face surveys for two reasons. First, the interviewer is exposed to the potentially biasing effect of the respondent's appearance and environment in addition to their voice. Second, the interviewer may inadvertently give respondents nonverbal as well as verbal cues about how they should respond. Interviewing skills do not come naturally to people because a standardized interview violates some of the normative rules of efficient conversation. For instance, interviewers must read all questions and response options exactly as written rather than paraphrasing them, since even small changes in wording have the potential to influence survey outcomes. Interviewers also have to ask a question even when the respondent has already volunteered the answer. To reduce bias as well as to avoid interviewer effects, that is, the tendency for the data collected by different interviewers to differ due to procedural inconsistency, large investments must typically be made in providing interviewers the necessary training and practice. Data analyses of face-to-face surveys should also examine and report on any significant interviewer effects identified in the data.

In summary, face-to-face surveys offer many advantages over mail and telephone surveys in terms of the complexity and quality of the data collected, but these advantages come with significantly increased logistical costs as well as additional potential sources of response bias. The costs are in fact so prohibitive that face-to-face surveys are typically employed only when telephone surveys are impractical, for example, when the questionnaire is too long or complex to deliver over the phone or when a significant proportion of the population of interest lacks telephone access.

Facet Theory

Facet theory (FT) is a methodology that may be considered an extension of methods for the design and analysis of experiments. Experiments use one or more factors that characterize the conditions under

$\mathbf{R}$ is recorded for each such person-question crossing, we have the mapping $\mathbf{P} \times \mathbf{Q} \rightarrow \mathbf{R}$.

Things become more interesting when $\mathbf{Q}$ (and $\mathbf{P}$) are *facetized* and embedded into the relational context of a *mapping sentence*. For example, one may want to assess the intelligence of students by different types of test items that satisfy the following definition:

Student (p) solves a		
$\mathbf{Q}_1 = \text{language}$		$\mathbf{Q}_2 = \text{operation}$
(numerical)		(finding)
(geometrical)	task that requires	(applying)
(verbal)		(learning)
	$\mathbf{R} = \text{range}$	
	(right)	
	(to)	in the sense of the objective rule
	(wrong)	

which the variables of interest are observed. Data analysis, then, studies the effects of these factors on the dependent variables. FT extends these notions to the social sciences, proposing to systematically design the researcher's questions and items over a framework of facets, and then study the resulting data with data analytic tools that ask how these facets show up in the observations [2].

Facet Design

Designing observations in FT means, first of all, characterizing them in terms of *facets*. A facet is a variable that allows one to sort objects of interest into different classes. For example, 'gender' is a facet that sorts persons into the classes male and female. Similarly, 'mode of attitude' serves to classify attitudinal behavior as either emotional, cognitive, or overt action.

In survey research, facets are used routinely to stratify a population $\mathbf{P}$ in order to generate samples with guaranteed distributions on important background variables. The same idea can be carried over to the *universe of questions* ($\mathbf{Q}$): introducing *content facets* and systematically crossing them defines various types of questions. Finally, the third component in an empirical query is the set of responses ($\mathbf{R}$) that are considered relevant when $\mathbf{P}$ is confronted with $\mathbf{Q}$. In the usual case, where each person in $\mathbf{P}$ is given every question in $\mathbf{Q}$, and exactly one response out of

A mapping sentence interconnects the facets and clarifies their roles within the context of a particular *content domain*. The example shows that $\mathbf{Q}_2 = \text{'operation'}$ is the *stem* facet, while $\mathbf{Q}_1 = \text{'language'}$ is a *modifying* facet for IQ tasks belonging to the design $\mathbf{Q}_1 \times \mathbf{Q}_2$. The population facet $\mathbf{P}$ is not further facetized here. The mapping sentence for $\mathbf{P} \times \mathbf{Q}_1 \times \mathbf{Q}_2 \rightarrow \mathbf{R}$ serves as a blueprint for systematically constructing concrete test items. The two $\mathbf{Q}$ -facets can be fully crossed, and so there are nine types of tasks. For example, we may want to construct tasks that assess the student's ability to apply (A) or to find (F) rules, both with numerical (N) and geometrical (G) tasks. This yields four types of tasks, each characterized by a combination (*structuple*) such as AN, AG, FN, or FG.

The structuple, however, only describes an item's question part. The item is incomplete without its range of admissible answers. In the above example, the *range facet* ($\mathbf{R}$) is of particular interest, because it represents a *common* range for all questions that can be constructed within this definitional framework. Indeed, according to Guttman [6], an intelligence item can be distinguished from other items (e.g., such as attitude items) by satisfying exactly this range. That is, an item is an intelligence item if and only if the answers to its question are mapped onto a right-to-wrong (according to a logical, scientific, or factual rule) continuum.

Mapping sentences are useful devices for conceptually organizing a domain of research questions. They enable the researcher to structure a universe

2 Facet Theory

of items and to systematically construct a sample of items that belong to this universe. Mapping sentences are, however, not a tool that automatically yields meaningful results. One needs solid substantive knowledge and clear semantics to make them work.

Correspondence Hypotheses Relating Design to Data

A common range of items gives rise to certain *monotonicity hypotheses*. For intelligence items, Guttman [6] predicts that they correlate nonnegatively among each other, which is confirmed for the case shown in Table 1. This ‘first law of intelligence’ is a well-established empirical regularity for the universe of intelligence items. A similar law holds for attitude items.

A more common-place hypothesis in FT is to check whether the various facets of the study’s design show up, in one way or another, in the structure of the data. More specifically, one often uses the *discrimination hypothesis* that the distinctions a facet makes for the types of observations should be reflected in differences of the data for these types. Probably, the most successful variant of this hypothesis is that the **Q**-facets should allow one to partition a space

that represents the items’ empirical similarities into simple *regions*. Figure 1 shows three prototypical patterns that often result in this context. The space here could be an **multidimensional scaling** (MDS) representation of the intercorrelations of a battery of items. The plots are *facet diagrams*, where the points are replaced by the element (*struct*) that the item represented by a particular point has on a particular facet. Hence, if we look at the configuration in terms of facet 1 (left panel), the points form a pattern that allows us to cut the plane into parallel stripes. If the facet were ordered so that $a < b < c$, this *axial* pattern leads to an embryonic dimensional interpretation of the X-axis. The other two panels of Figure 1 show patterns that are also often found in real applications, that is, a *modular* and a *polar* regionalization, respectively. Combined, these prototypes give rise to various partitionings such as the *radex* (a modular combined with a polar facet) or the *duplex* (two axial facets). Each such pattern is found by partitioning the space facet by facet.

A third type of correspondence hypothesis used in FT exists for design (or data) structuples whose facets are all ordered in a common sense. Elizur [3], for example, asked persons to indicate whether they were

Table 1 Intercorrelations of eight intelligence test items (Guttman, 1965)

Structuple	Task	1	2	3	4	5	6	7	8
NA	1	1.00							
NA	2	0.67	1.00						
NF	3	0.40	0.50	1.00					
GF	4	0.19	0.26	0.52	1.00				
GF	5	0.12	0.20	0.39	0.55	1.00

Table 2 Profiles of concern [3]

Profile	A = interest	B = expertise	C = stability	D = employment	Freq.
1	0	0	0	0	85
2	0	0	0	1	38
3	0	0	1	0	28
4	1	0	0	0	3
5	0	1	0	1	18
6	0	0	1	1	37
7	1	0	1	0	2
8	1	1	0	0	5
9	0	1	1	1	5
10	1	0	1	1	2
11	1	1	1	0	2
12	1	1	1	1	53

concerned or not about losing certain features of their job after the introduction of computers to their workplace. The design of this study was ‘Person (p) is concerned about losing $\rightarrow \mathbf{A} \times \mathbf{B} \times \mathbf{C} \times \mathbf{D}$ ’, where **A** = ‘interest (yes/no)’, **B** = ‘experience (yes/no)’, **C** = ‘stability (yes/no)’, and **D** = ‘employment (yes/no)’. Each person generated an answer profile with four elements such as 1101 or 0100, where 1 = yes and 0 = no. Table 2 lists 98% of the observed profiles. We now ask whether these profiles form a Guttman scale [4] or, if not, whether they form a partial order with nontrivial properties. For example, the partial order may be flat in the sense that it can be represented in a plane such that its Hasse diagram has no paths that cross each other outside of common points (*diamond*). If so, it can be explained by two dimensions [10].

A soft variant of relating structuples to data is the hypothesis that underlies *multidimensional scalogram analysis* or MSA [9]. It predicts that given design (or data) structuples can be placed into in a multidimensional space of given dimensionality so that this space can be partitioned, facet by facet, into simple regions as shown, for example, in Figure 1. (Note though that MSA does not involve first computing any overall proximities. It also places no requirements on the scale level of the facets of the structuples.)

Facet-theoretical Data Analysis

Data that are generated within a facet-theoretical design are often analyzed by special data analytic methods or by traditional statistics used in particular ways. An example for the latter is given in Figure 2.

Figure 2 MDS representation of correlations of Table 1 (left panel) and partitioning by facets ‘language’ and ‘operation’ (right panel)

Figure 3 Structure of the universe of intelligence test items

Its left panel shows a two-dimensional multidimensional scaling space for the data in Table 1. The right panel of this figure demonstrates that the space can be divided by each of the two design facets, ‘language’ and ‘operation’, into two regions. Each region contains only items of one particular type. The resulting pattern partially confirms a structure found for the universe of typical paper-and-pencil intelligence test items. The universe has an additional facet (‘mode of communicating’) that shows up as the axis of the *cylindrex* shown in Figure 3. One also notes that the facet ‘operation’ turns out to be ordered, which stimulates theoretical thinking aimed at explaining this more formally.

Partial order hypotheses for structuples can be checked by POSAC (partial order structuple analysis with coordinates; [8]). POSAC computer programs are available within SYSTAT or HUDAP [1]. Figure 4 shows a POSAC solution for the data in Table 2. The 12 profiles here are represented as points. Two points are connected by a line if their profiles can be ordered such that profile x is ‘higher’ (in the sense of the common range ‘concern’) than profile y on at least one facet and not lower on any other facet. One notes that the profiles on each path that is monotonic with respect to the joint direction – as, for example, the chain 1-2-5-9-12 – form a perfect Guttman scale (see **Unidimensional Scaling**). One also notes that the various paths in the partial order do not cross each other except possibly in points that they share. Hence, the partial order is

Figure 4 POSAC solution for the data in Table 2

flat and can be explained by two dimensions. Dimension 1 has a simple relation to facet **D**: all profiles that have a low value on that dimension have a zero on **D**, that is, these persons are not concerned about losing their employment; all profiles with high values on dimension 1 are high on **D**. Dimension 2 has a similar relation to facet **A**. Hence, facets **D** and **A** explain the dimensions. The remaining two facets play secondary roles in this context: **B** is ‘accentuating’ [10] in the sense that persons who agree to

B are very high on at least one of the base dimensions. **C**, in contrast, is ‘attenuating’ so that persons high on **C** are relatively similar on their *X* and *Y* coordinates. Both secondary facets thus generate additional cutting points and thereby more intervals on the base dimensions.

HUDAP also contains programs for doing MSA. MSA is seldom used in practice, because its solutions are rather indeterminate [2]. They can be transformed in many ways that can radically change their appearance, which makes it difficult to interpret and to replicate them. One can, however, make MSA solutions more robust by enforcing additional constraints such as linearity onto the boundary lines or planes [9]. Such constraints are not related to content and for that reason rejected by many facet theorists who prefer data analysis that is as ‘intrinsic’ [7] as possible. On the other hand, if a good MSA solution is found under ‘extrinsic’ side constraints, it certainly also exists for the softer intrinsic model.

Factor Analysis: Confirmatory

Of primary import to **factor analysis**, in general, is the notion that some variables of theoretical interest cannot be observed directly; these unobserved variables are termed **latent variables** or *facto-
tors*. Although latent variables cannot be measured directly, information related to them can be obtained indirectly by noting their effects on observed variables that are believed to represent them. The oldest and best-known statistical procedure for investigating relations between sets of observed and latent variables is that of factor analysis. In using this approach to data analyses, researchers examine the covariation among a set of observed variables in order to gather information on the latent constructs (i.e., factors) that underlie them. In factor analysis models, each observed variable is hypothesized to be determined by two types of influences: (a) the latent variables (factors) and (b) unique variables (called either *residual* or *error variables*). The strength of the relation between a factor and an observed variable is usually termed the *loading of the variable* on the factor.

Exploratory versus Confirmatory Factor Analysis

There are two basic types of factor analyses: exploratory factor analysis (EFA) and confirmatory factor analysis (CFA). EFA is most appropriately used when the links between the observed variables and their underlying factors are unknown or uncertain. It is considered to be exploratory in the sense that the researcher has no prior knowledge that the observed variables do, indeed, measure the intended factors. Essentially, the researcher uses EFA to determine factor structure. In contrast, CFA is appropriately used when the researcher has some knowledge of the underlying latent variable structure. On the basis of theory and/or empirical research, he or she postulates relations between the observed measures and the underlying factors *a priori*, and then tests this hypothesized structure statistically. More specifically, the CFA approach examines the extent to which a highly constrained *a priori* factor structure is consistent with the sample data. In summarizing the primary distinction between the two methodologies, we can say

that whereas EFA operates inductively in allowing the observed data to determine the underlying factor structure *a posteriori*, CFA operates deductively in postulating the factor structure *a priori* [5].

Of the two factor analytic approaches, CFA is by far the more rigorous procedure. Indeed, it enables the researcher to overcome many limitations associated with the EFA model; these are as follows: First, whereas the EFA model assumes that all common factors are either correlated or uncorrelated, the CFA model makes no such assumptions. Rather, the researcher specifies, *a priori*, only those factor correlations that are considered to be substantively meaningful. Second, with the EFA model, all observed variables are directly influenced by all common factors. With CFA, each factor influences only those observed variables with which it is purported to be linked. Third, whereas in EFA, the unique factors are assumed to be uncorrelated, in CFA, specified covariation among particular uniquenesses can be tapped. Finally, provided with a malfitting model in EFA, there is no mechanism for identifying which areas of the model are contributing most to the misfit. In CFA, on the other hand, the researcher is guided to a more appropriately specified model via indices of misfit provided by the statistical program.

Hypothesizing a CFA Model

Given the *a priori* knowledge of a factor structure and the testing of this factor structure based on the analysis of covariance structures, CFA belongs to a class of methodology known as **structural equation modeling** (SEM). The term structural equation modeling conveys two important notions: (a) that structural relations can be modeled pictorially to enable a clearer conceptualization of the theory under study, and (b) that the causal processes under study are represented by a series of structural (i.e., regression) equations. To assist the reader in conceptualizing a CFA model, I now describe the specification of a hypothesized CFA model in two ways; first, as a graphical representation of the hypothesized structure and, second, in terms of its structural equations.

Graphical Specification of the Model

CFA models are schematically portrayed as path diagrams (see **Path Analysis and Path Diagrams**) through the incorporation of four geometric symbols: a circle (or ellipse) representing unobserved

Figure 1 Hypothesized CFA model

latent factors, a square (or rectangle) representing observed variables, a single-headed arrow ($\rightarrow$) representing the impact of one variable on another, and a double-headed arrow ($\leftrightarrow$) representing covariance between pairs of variables. In building a CFA model, researchers use these symbols within the framework of three basic configurations, each of which represents an important component in the analytic process. We turn now to the CFA model presented in Figure 1, which represents the postulated four-factor structure of nonacademic self-concept (SC) as tapped by items comprising the Self Description Questionnaire-I (SDQ-I; [15]). As defined by the SDQ-I, nonacademic SC embraces the constructs of physical and social SCs.

On the basis of the geometric configurations noted above, decomposition of this CFA model conveys the following information: (a) there are four factors, as indicated by the four ellipses labeled Physical SC (Appearance; F1), Physical SC (Ability; F2), Social SC (Peers; F3), and Social SC (Parents; F4); (b) the four factors are intercorrelated, as indicated by the six two-headed arrows; (c) there are 32 observed variables, as indicated by the 32 rectangles (SDQ1-SDQ66); each represents one item from the SDQ-I; (d) the observed variables measure the factors in the following pattern: Items 1, 8, 15, 22, 38, 46, 54, and 62 measure Factor 1, Items 3, 10, 24, 32, 40, 48, 56, and 64 measure Factor 2, Items 7, 14, 28, 36, 44, 52, 60, and 69 measure Factor 3, and Items 5, 19, 26, 34, 42, 50, 58, and 66 measure Factor 4; (e) each observed variable measures one and only one factor; and (f) errors of measurement associated with each observed variable (E1-E66) are uncorrelated (i.e., there are no double-headed arrows connecting any two error terms. Although the error variables, technically speaking, are unobserved variables, and should have ellipses around them, common convention in such diagrams omits them in the interest of clarity.

In summary, a more formal description of the CFA model in Figure 1 argues that: (a) responses to the SDQ-I are explained by four factors; (b) each item has a nonzero loading on the nonacademic SC factor it was designed to measure (termed *target loadings*), and zero loadings on all other factors (termed *nontarget loadings*); (c) the four factors are correlated; and (d) measurement error terms are uncorrelated.

Structural Equation Specification of the Model

From a review of Figure 1, you will note that each observed variable is linked to its related factor by a single-headed arrow pointing *from* the factor *to* the observed variable. These arrows represent regression paths and, as such, imply the influence of each factor in predicting its set of observed variables. Take, for example, the arrow pointing from Physical SC (Ability) to SDQ1. This symbol conveys the notion that responses to Item 1 of the SDQ-I assessment measure are 'caused' by the underlying construct of physical SC, as it reflects one's perception of his or her physical ability. In CFA, these symbolized regression paths represent factor loadings and, as with all factor analyses, their strength is of primary interest. Thus, specification of a hypothesized model focuses on the formulation of equations that represent these structural regression paths. Of secondary importance are any covariances between the factors and/or between the measurement errors.

The building of these equations, in SEM, embraces two important notions: (a) that any variable in the model having an arrow pointing at it represents a dependent variable, and (b) dependent variables are always explained (i.e., accounted for) by other variables in the model. One relatively simple approach to formulating these structural equations, then, is first to note each dependent variable in the model and then to summarize all influences on these variables. Turning again to Figure 1, we see that there are 32 variables with arrows pointing toward them; all represent observed variables (SDQ1-SDQ66). Accordingly, these regression paths can be summarized in terms of 32 separate equations as follows:

$$\begin{aligned}
 \text{SDQ1} &= \text{F1} + \text{E1} \\
 \text{SDQ8} &= \text{F1} + \text{E8} \\
 \text{SDQ15} &= \text{F1} + \text{E15} \\
 &\vdots \\
 \text{SDQ62} &= \text{F1} + \text{E62} \\
 \text{SDQ3} &= \text{F2} + \text{E3} \\
 \text{SDQ10} &= \text{F2} + \text{E10} \\
 &\vdots \\
 \text{SDQ64} &= \text{F2} + \text{E64} \\
 \text{SDQ7} &= \text{F3} + \text{E7} \\
 \text{SDQ14} &= \text{F3} + \text{E14} \\
 &\vdots \\
 \text{SDQ69} &= \text{F3} + \text{E69}
 \end{aligned}$$

$$\begin{aligned}
 \text{SDQ5} &= \text{F4} + \text{E5} \\
 \text{SDQ19} &= \text{F4} + \text{E19} \\
 &\vdots \\
 \text{SDQ66} &= \text{F4} + \text{E66}
 \end{aligned}
 \tag{1}$$

Although, in principle, there is a one-to-one correspondence between the schematic presentation of a model and its translation into a set of structural equations, it is important to note that neither one of these representations tells the whole story. Some parameters, critical to the estimation of the model, are not explicitly shown and thus may not be obvious to the novice CFA analyst. For example, in both the schematic model (see Figure 1) and the linear structural equations cited above, there is no indication that either the factor variances or the error variances are parameters in the model. However, such parameters are essential to all structural equation models and therefore must be included in the model specification. Typically, this specification is made via a separate program command statement, although some programs may incorporate default values. Likewise, it is equally important to draw your attention to the specified nonexistence of certain parameters in a model. For example, in Figure 1, we detect no curved arrow between E1 and E8, which would suggest the lack of covariance between the error terms associated with the observed variables SDQ1 and SDQ8. (Error covariances can reflect overlapping item content and, as such, represent the same question being asked, but with a slightly different wording.)

Testing a Hypothesized CFA Model

Testing for the validity of a hypothesized CFA model requires the satisfaction of certain statistical assumptions and entails a series of analytic steps. Although a detailed review of this testing process is beyond the scope of the present chapter, a brief outline is now presented in an attempt to provide readers with at least a flavor of the steps involved. (For a non-mathematical and paradigmatic introduction to SEM based on three different programmatic approaches to the specification and testing of a variety of basic CFA models, readers are referred to [6–9]; for a more detailed and analytic approach to SEM, readers are referred to [3], [14], [16] and [17].)

Statistical Assumptions

As with other multivariate methodologies, SEM assumes that certain statistical conditions have been met. Of primary importance is the assumption that the data are multivariate normal (see **Catalogue of Probability Density Functions**). In essence, the concept of multivariate normality embraces three requirements: (a) that the univariate distributions are normal; (b) that the joint distributions of all variable combinations are normal; and (c) that all bivariate scatterplots are linear and homoscedastic [14]. Violations of multivariate normality can lead to the distortion of goodness-of-fit indices related to the model as a whole (see e.g., [12]; [10]; and (see **Goodness of Fit**) to positively biased tests of significance related to the individual parameter estimates [14]).

Estimating the Model

Once the researcher determines that the statistical assumptions have been met, the hypothesized model can then be tested statistically in a simultaneous analysis of the entire system of variables. As such, some parameters are freely estimated while others remain fixed to zero or some other nonzero value. (Nonzero values such as the 1's specified in Figure 1 are typically assigned to certain parameters for purposes of model identification and latent factor scaling.) For example, as shown in Figure 1, and in the structural equation above, the factor loading of SDQ8 on Factor 1 is freely estimated, as indicated by the single-headed arrow leading from Factor 1 to SDQ8. By contrast, the factor loading of SDQ10 on Factor 1 is not estimated (i.e., there is no single-headed arrow leading from Factor 1 to SDQ10); this factor loading is automatically fixed to zero by the program. Although there are four main methods for estimating parameters in CFA models, **maximum likelihood estimation** remains the one most commonly used and is the default method for all SEM programs.

Evaluating Model Fit

Once the CFA model has been estimated, the next task is to determine the extent to which its specifications are consistent with the data. This evaluative process focuses on two aspects: (a) goodness-of-fit of the model as a whole, and (b) goodness-of-fit of individual parameter estimates. Global assessment of fit

is determined through the examination of various fit indices and other important criteria. In the event that goodness-of-fit is adequate, the model argues for the plausibility of postulated relations among variables; if it is inadequate, the tenability of such relations is rejected. Although there is now a wide array of fit indices from which to choose, typically only one or two need be reported, along with other fit-related indicators. A typical combination of these evaluative criteria might include the Comparative Fit Index (CFI; Bentler, [1]), the standardized root mean square residual (SRMR), and the Root Mean Square Error of Approximation (RMSEA; [18]), along with its 90% confidence interval. Indicators of a well-fitting model would be evidenced from a CFI value equal to or greater than .93 [11], an SRMR value of less than .08 [11], and an RMSEA value of less than .05 [4].

Goodness-of-fit related to individual parameters of the model focuses on both the appropriateness (i.e., no negative variances, no correlations >1.00) and statistical significance (i.e., estimate divided by standard error >1.96) of their estimates. For parameters to remain specified in a model, their estimates must be statistically significant.

Post Hoc Model-fitting

Presented with evidence of a poorly fitting model, the hypothesized CFA model would be rejected. Analyses then proceed in an exploratory fashion as the researcher seeks to determine which parameters in the model are misspecified. Such information is gleaned from program output that focuses on modification indices (MIs), estimates that derive from testing for the meaningfulness of all constrained (or fixed) parameters in the model. For example, the constraint that the loading of SDQ10 on Factor 1 is zero, as per Figure 1 would be tested. If the MI related to this fixed parameter is large, compared to all other MIs, then this finding would argue for its specification as a freely estimated parameter. In this case, the new parameter would represent a loading of SDQ10 on both Factor 1 and Factor 2. Of critical importance in *post hoc* model-fitting, however, is the requirement that only substantively meaningful parameters be added to the original model specification.

Interpreting Estimates

Shown in Figure 2 are standardized parameter estimates resulting from the testing of the hypothesized CFA model portrayed in Figure 1. Standardization transforms the solution so that all variables have a variance of 1; factor loadings will still be related in the same proportions as in the original solution, but parameters that were originally fixed will no longer have the same values. In a standardized solution, factor loadings should generally be less than 1.0 [14].

Turning first to the factor loadings and their associated errors of measurement, we see that, for example, the regression of Item SDQ15 on Factor 1 (Physical SC; Appearance) is .82. Because SDQ15 loads only on Factor 1, we can interpret this estimate as indicating that Factor 1 accounts for approximately 67% ($100 \times .82^2$) of the variance in this item. The measurement error coefficient associated with SDQ15 is .58, thereby indicating that some 34% (as a result of decimal rounding) of the variance associated with this item remains unexplained by Factor 1. (It is important to note that, unlike the LISREL program [13], which does not standardize errors in variables, the EQS program [2] used here does provide these standardized estimated values; *see Structural Equation Modeling: Software*.)

Finally, values associated with the double-headed arrows represent latent factor correlations. Thus, for example, the value of .41 represents the correlation between Factor 1 (Physical SC; Appearance) and Factor 2 (Physical SC; Ability). These factor correlations should be consistent with the theory within which the CFA model is grounded.

In conclusion, it is important to emphasize that only issues related to the specification of first-order CFA models, and only a cursory overview of the steps involved in testing these models has been included here. Indeed, sound application of SEM procedures in testing CFA models requires that researchers have a comprehensive understanding of the analytic process. Of particular importance are issues related to the assessment of multivariate normality, appropriateness of sample size, use of incomplete data, correction for nonnormality, model specification, identification, and estimation, evaluation of model fit, and post hoc model-fitting. Some of these topics are covered in other entries, as well as the books and journal articles cited herein.

Factor Analysis: Exploratory

Introduction

This year marks the one hundredth anniversary for exploratory factor analysis (EFA), a method introduced by **Charles Spearman** in 1904 [21]. It is testimony to the deep insights of Spearman as well as many who followed that EFA continues to be central to **multivariate analysis** so many years after its introduction. In a recent search of electronic sources, where I restricted attention to the psychological and social sciences (using PsychINFO), more than 20 000 articles and books were identified in which the term ‘factor analysis’ had been used in the summary, well over a thousand citations from the last decade alone.

EFA, as it is known today, was for many years called common factor analysis. The method is in some respects similar to another well-known method called **principal component analysis** (PCA) and because of various similarities, these methods are frequently confused. One of the purposes of this article will be to try to dispel at least some of the confusion.

The general methodology currently seen as an umbrella for both exploratory factor analysis and confirmatory factor analysis (*see* **Factor Analysis: Confirmatory**) is called **structural equation modeling** (SEM) Although EFA can be described as an exploratory or unrestricted structural equation model, it would be a shame to categorize EFA as nothing more than a SEM, as doing so does an injustice to its long history as the most used and most studied latent variable method in the social and behavioral sciences. This is somewhat like saying that **analysis of variance** (ANOVA) which has been on the scene for more than seventy-five years and which is prominently related to experimental design, is just a **multiple linear regression** model. There is some truth to each statement, but it is unfair to the rich histories of EFA and ANOVA to portray their boundaries so narrowly.

A deeper point about the relationships between EFA and SEM is that these methods appeal to very different operational philosophies of science. While SEMs are standardly seen as founded on rather strict hypothetico-deductive logic, EFAs are

not. Rather, EFA generally invokes an exploratory search for structure that is open to new structures not imagined prior to analysis. Rozeboom [20] has carefully examined the logic of EFA, using the label *explanatory induction* to describe it; this term neatly summarizes EFA’s reliance on data to induce hypotheses about structure, and its general concern for explanation.

Several recent books, excellent reviews, and constructive critiques of EFA have become available to help understand its long history and its potential for effective use in modern times [6, 8, 15, 16, 23, 25]. A key aim of this article is to provide guidance with respect to literature about factor analysis, as well as to software to aid applications.

Basic Ideas of EFA Illustrated

Given a matrix of correlations or covariances (*see* **Correlation and Covariance Matrices**) among a set of manifest or observed variables, EFA entails a model whose aim is to explain or account for correlations using a smaller number of ‘underlying variables’ called common factors. EFA postulates common factors as **latent variables** so they are unobservable in principle. Spearman’s initial model, developed in the context of studying relations among psychological measurements, used a single common factor to account for all correlations among a battery of tests of intellectual ability. Starting in the 1930s, **Thurstone** generalized the ‘two-factor’ method of Spearman so that EFA became a multiple (common) factor method [22]. In so doing, Thurstone effectively broadened the range of prospective applications in science. The basic model for EFA today remains largely that of Thurstone. EFA entails an assumption that there exist uniqueness factors as well as common factors, and that these two kinds of factors complement one another in mutually orthogonal spaces. An example will help clarify the central ideas.

Table 1 below contains a correlation matrix for all pairs of five variables, the first four of which correspond to ratings by the seventeenth century art critic de Piles (using a 20 point scale) of 54 painters for whom data were complete [7]. Works of these painters were rated on four characteristics: composition, drawing, color, and expression. Moreover, each painter was associated with a particular ‘School.’ For current purposes, all information about Schools is

2 Factor Analysis: Exploratory

Table 1 Correlations among pairs of variables, painter data of [8]

	Composition	Drawing	Color	Expression	School D
Composition	1.00				
Drawing	0.42	1.00			
Color	-0.10	-0.52	1.00		
Expression	0.66	0.57	-0.20	1.00	
School D	-0.29	-0.36	0.53	-0.45	1.00

ignored except for distinguishing the most distinctive School D (Venetian) from the rest using a binary variable. For more details, see the file ‘painters’ in the Modern Applied Statistics with S (MASS) library in R or Splus software (see **Software for Statistical Analyses**), and note that the original data and several further analyses can be found in the MASS library [24].

Table 1 exhibits correlations among the painter variables, where upper triangle entries are ignored since the matrix is symmetric. Table 2 exhibits a common factor coefficients matrix (of order 5×2) that corresponds to the initial correlations, where entries of highest magnitude are in bold print. The final column of Table 2 is labeled h^2 , the standard notation for variable communalities. Because these factor coefficients correspond to an orthogonal factor solution, that is, uncorrelated common factors, each communality can be reproduced as a (row) sum of squares of the two factor coefficients to its left; for example $(0.76)^2 + (-0.09)^2 = 0.59$. The columns labeled 1 and 2 are factor loadings, each of which is properly interpreted as a (product-moment) correlation between one of the original manifest variables (rows) and a derived common factor (columns). Post-multiplying the factor coefficient matrix by its transpose yields numbers that

approximate the corresponding entries in the correlation matrix. For example, the *inner product* of the rows for Composition and Drawing is $0.76 \times 0.50 + (-0.09) \times (-0.56) = 0.43$, which is close to 0.42, the observed correlation; so the corresponding residual equals -0.01 . Pairwise products for all rows reproduce the observed correlations in Table 1 quite well as only one residual fit exceeds 0.05 in magnitude, and the mean residual is 0.01.

The final row of Table 2 contains the average sum of squares for the first two columns; the third entry is the average of the communalities in the final column, as well as the sum of the two average sums of squares to its left: $0.31 + 0.28 \approx 0.60$. These results demonstrate an additive decomposition of common variance in the solution matrix where 60 percent of the total variance is common among these five variables, and 40 percent is uniqueness variance.

Users of EFA have often confused communality with reliability, but these two concepts are quite distinct. Classical common factor and psychometric test theory entail the notion that the uniqueness is the sum of two (orthogonal) parts, specificity and error. Consequently, uniqueness variance is properly seen as an upper bound for error variance; alternatively, communality is in principle a lower bound for reliability. It might help to understand this by noting that each EFA entails analysis of just a sample of observed variables or measurements in some domain, and that the addition of more variables within the general domain will generally increase shared variance as well as individual communalities. As battery size is increased, individual communalities increase toward upper limits that are in principle close to variable reliabilities. See [15] for a more elaborate discussion.

To visualize results for my example, I plot the common factor coefficients in a plane, after making some modifications in signs for selected rows and the second column. Specifically, I reverse the signs of the 3rd and 5th rows, as well as in the second column, so that all values in the factor coefficients matrix become

Table 2 Factor loadings for 2-factor EFA solution, painter data

	Factor		
Variable name	1	2	h^2
Composition	0.76	-0.09	0.59
Drawing	0.50	-0.56	0.56
Color	-0.03	0.80	0.64
Expression	0.81	-0.26	0.72
School D	-0.30	0.62	0.47
Avg. Col. SS	0.31	0.28	0.60

positive. Changes of this sort are always permissible, but we need to keep track of the changes, in this case by renaming the third variable to 'Color[-1]' and the final binary variable to 'School.D[-1]'. Plotting the revised coefficients by rows yields the five labeled points of Figure 1.

In addition to plotting points, I have inserted vectors to correspond to 'transformed' factors; the arrows show an 'Expression-Composition' factor and a second, correlated, 'Drawing-Color[-1]' factor. That the School.D variable also loads highly on this second factor, and is also related to, that is, not orthogonal to, the point for Expression, shows that mean ratings, especially for the Drawing, Expression, and Color variates (the latter in an opposite direction), are notably different between Venetian School artists and painters from the collection of other schools. This can be verified by examination of the correlations (sometimes called point biserials) between the School.D variable and all the ratings variables in Table 1; the skeptical reader can easily acquire these data and study details. In fact, one of the reasons for choosing this example was to show that EFA as an exploratory data analytic method can help in studies of relations among quantitative and categorical variables. Some connections of EFA with other methods will be discussed briefly in the final section.

In modern applications of factor analysis, investigators ordinarily try to name factors in terms of dimensions of individual difference variation, to

identify latent variables that in some sense appear to 'underlie' observed variables. In this case, my ignorance of the works of these classical painters, not to mention of the thinking of de Piles as related to his ratings, led to my literal, noninventive factor names.

Before going on, it should be made explicit that insertion of the factor-vectors into this plot, and the attempt to name factors, are best regarded as discretionary parts of the EFA enterprise. The key output of such an analysis is the identification of the subspace defined by the common factors, within which variables can be seen to have certain distinctive structural relationships with one another. In other words, it is the configuration of points in the derived space that provides the key information for interpreting factor results; a relatively low-dimensional subspace provides insights into structure, as well as quantification of how much variance variables have in common. Positioning or naming of factors is generally optional, however common. When the common number of derived factors exceeds two or three, factor transformation is an almost indispensable part of an EFA, regardless of whether attempts are made to name factors.

Communalities generally provide information as to how much variance variables have in common or share, and can sometimes be indicative of how highly predictable variables are from one another. In fact, the squared multiple correlation of each variable with all others in the battery is often recommended as an initial estimate of communality for each variable. Communalities can also signal (un)reliability, depending on the composition of the battery of variables, and the number of factors; recall the foregoing discussion on this matter.

Note that there are no assumptions that point configurations for variables must have any particular form. In this sense, EFA is more general than many of its counterparts. Its exploratory nature also means that prior structural information is usually not part of an EFA, although this idea will eventually be qualified in the context of reviewing factor transformations. Even so, clusters or hierarchies of either variables or entities may sometimes be identified in EFA solutions. In our example, application of the common factor method yields a relatively parsimonious model in the sense that two common factors account for all relationships among variables. However, EFA was, and is usually, antiparsimonious in another sense as there is one uniqueness factor for each variable as

Figure 1 Plot of variables-as-points in 2-factor space, painter data

well as common factors to account for all entries in the correlation table.

Some Relationships Between EFA and PCA

As noted earlier, EFA is often confused with PCA. In fact, misunderstanding occurs so often in reports, published articles, and textbooks that it will be useful to describe how these methods compare, at least in a general way. More detailed or more technical discussions concerning such differences is available in [15].

As noted, the key aim of EFA is usually to derive a relatively small number of common factors to explain or account for (off-diagonal) covariances or correlations among a set of observed variables. However, despite being an exploratory method, EFA entails use of a falsifiable *model* at the level of manifest observations or correlations (covariances). For such a model to make sense, relationships among manifest variables should be approximately linear. When approximate linearity does not characterize relationships among variables, attempts can be made to transform (at least some of) the initial variables to ‘remove bends’ in their relationships with other variables, or perhaps to remove outliers. Use of square root, logarithmic, reciprocal, and other nonlinear transformations are often effective for such purposes. Some investigators question such steps, but rather than asking why nonlinear transformations should be considered, a better question usually is, ‘Why should the analyst believe the metric used at the outset for particular variables should be expected to render relationships linear, without reexpressions or transformations?’ Given at least approximate linearity among all pairs of variables – the inquiry about which is greatly facilitated by examining pairwise scatterplots among all pairs of variables – common factor analysis can often facilitate explorations of relationships among variables. The prospects for effective or productive applications of EFA are also dependent on thoughtful efforts at the stage of study design, a matter to be briefly examined below. With reference to our example, the pairwise relationships between the various pairs of de Pile’s ratings of painters were found to be approximately linear.

In contrast to EFA, principal components analysis does *not* engage a model. PCA generally entails

an algebraic decomposition of an initial data matrix into mutually orthogonal derived variables called *components*. Alternatively, PCA can be viewed as a linear transformation of the initial data vectors into uncorrelated variates with certain optimality properties. Data are usually centered at the outset by subtracting means for each variable and then scaled so that all variances are equal, after which the (rectangular) data matrix is resolved using a method called *singular value decomposition* (SVD). Components from a SVD are usually ordered so that the first component accounts for the largest amount of variance, the second the next largest amount, subject to the constraint that it be uncorrelated with the first, and so forth. The first few components will often summarize the majority of variation in the data, as these are principal components. When used in this way, PCA is justifiably called a *data reduction* method and it has often been successful in showing that a rather large number of variables can be summarized quite well using a relatively small number of derived components.

Conventional PCA can be completed by simply computing a table of correlations of each of the original variables with the chosen principal components; indeed doing so yields a PCA counterpart of the EFA coefficients matrix in Table 2 if two components are selected. Furthermore, sums of squares of correlations in this table, across variables, show the total variance each component explains. These component-level variances are the eigenvalues produced when the correlation matrix associated with the data matrix is resolved into eigenvalues and eigenvectors. Alternatively, given the original (centered and scaled) data matrix, and the eigenvalues and vectors of the associated correlation matrix, it is straightforward to compute principal components. As in EFA, derived PCA coefficient matrices can be rotated or transformed, and for purposes of interpretation this has become routine.

Given its algebraic nature, there is no particular reason for transforming variables at the outset so that their pairwise relationships are even approximately linear. This can be done, of course, but absent a model, or any particular justification for concentrating on pairwise *linear* relationships among variables, principal components analysis of correlation matrices is somewhat arbitrary. Because PCA is just an algebraic decomposition of data, it can be used for any kind of data; no constraints are made about the

dimensionality of the data matrix, no constraints on data values, and no constraints on how many components to use in analyses. These points imply that for PCA, assumptions are also optional regarding statistical distributions, either individually or collectively. Accordingly, PCA is a highly general method, with potential for use for a wide range of data types or forms. Given their basic form, PCA methods provide little guidance for answering model-based questions, such as those central to EFA. For example, PCA generally offers little support for assessing how many components ('factors') to generate, or try to interpret; nor is there assistance for choosing samples or extrapolating beyond extant data for purposes of statistical or psychometric generalization. The latter concerns are generally better dealt with using models, and EFA provides what in certain respects is one of the most general classes of models available.

To make certain other central points about PCA more concrete, I return to the correlation matrix for the painter data. I also conducted a PCA with two components (but to save space I do not present the table of 'loadings').

That is, I constructed the first two principal component variables, and found their correlations with the initial variables. A plot (not shown) of the principal component loadings analogous to that of Figure 1 shows the variables to be configured similarly, but all points are further from the origin. The row sums of squares of the component loadings matrix were 0.81, 0.64, 0.86, 0.83, and 0.63, values that correspond to communality estimates in the third column of the common factor matrix in Table 2. Across all five variables, PCA row sums of squares (which should not be called communalities) range from 14 to 37 percent larger than the h^2 entries in Table 2, an average of 27 percent; this means that component loadings are substantially larger in magnitude than their EFA counterparts, as will be true quite generally. For any data system, given the same number of components as common factors, component solutions yield row sums of squares that tend to be at least somewhat, and often markedly, larger than corresponding communalities.

In fact, these differences between characteristics of the PCA loadings and common factor loadings signify a broad point worthy of discussion. Given that principal components are themselves linear combinations of the original data vectors, each of the data variables tends to be part of the linear combination

with which it is correlated. The largest weights for each linear combination correspond to variables that most strongly define the corresponding linear combination, and so the corresponding correlations in the Principal Component (PC) loading matrix tend to be highest, and indeed to have spuriously high magnitudes. In other words, each PC coefficient in the matrix that constitutes the focal point for interpretation of results, tends to have a magnitude that is 'too large' because the corresponding variable is correlated partly with itself, the more so for variables that are largest parts of corresponding components. Also, this effect tends to be exacerbated when principal components are rotated. Contrastingly, common factors are latent variables, outside of the space of the data vectors, and common factor loadings are not similarly spurious. For example, EFA loadings in Table 2, being correlations of observed variables with latent variables, do not reflect self-correlations, as do their PCA counterparts.

The Central EFA Questions: How Many Factors? What Communalities?

Each application of EFA requires a decision about how many common factors to select. Since the common factor model is at best an approximation to the real situation, questions such as how many factors, or what communalities, are inevitably answered with some degree of uncertainty. Furthermore, particular features of given data can make formal fitting of an EFA model tenuous. My purpose here is to present EFA as a true exploratory method based on common factor principles with the understanding that formal 'fitting' of the EFA model is secondary to 'useful' results in applications; moreover, I accept that certain decisions made in contexts of real data analysis are inevitably somewhat arbitrary and that any given analysis will be incomplete. A wider perspective on relevant literature will be provided in the final section.

The history of EFA is replete with studies of how to select the number of factors; hundreds of both theoretical and empirical approaches have been suggested for the number of factors question, as this issue has been seen as basic for much of the past century. I shall summarize some of what I regard as the most enduring principles or methods, while trying to shed light on when particular methods are likely

6 Factor Analysis: Exploratory

to work effectively, and how the better methods can be attuned to reveal relevant features of extant data.

Suppose scores have been obtained on some number of correlated variables, say p , for n entities, perhaps persons. To entertain a factor analysis (EFA) for these variables generally means to undertake an exploratory structural analysis of linear relations among the p variables by analyzing a $p \times p$ covariance or correlation matrix. Standard outputs of such an analysis are a factor loading matrix for orthogonal or correlated common factors as well as communality estimates, and perhaps factor score estimates. All such results are conditioned on the number, m , of common factors selected for analysis. I shall assume that in deciding to use EFA, there is at least some doubt, *a priori*, as to how many factors to retain, so extant data will be the key basis for deciding on the number of factors. (I shall also presume that the data have been properly prepared for analysis, appropriate nonlinear transformations made, and so on, with the understanding that even outwardly small changes in the data can affect criteria bearing on the number of factors, and more.)

The reader who is even casually familiar with EFA is likely to have learned that one way to select the number of factors is to see how many **eigenvalues** (of the correlation matrix; recall PCA) exceed a certain criterion. Indeed, the ‘roots-greater-than-one’ rule has become a default in many programs. Alas, rules of this sort are generally too rigid to serve reliably for their intended purpose; they can lead either to overestimates or underestimates of the number of common factors. Far better than using any fixed cutoff is to understand certain key principles and then learn some elementary methods and strategies for choosing m . In some cases, however, two or more values of m may be warranted, in different solutions, to serve distinctive purposes for different EFAs of the same data.

A second thing even a nonspecialist may have learned is to employ a ‘scree’ plot (SP) to choose the number of factors in EFA. An SP entails plotting eigenvalues, ordered from largest to smallest, against their ordinal position, 1, 2, ..., and so on. Ordinarily, the SP is based on eigenvalues of a correlation matrix [5]. While the usual SP sometimes works reasonably well for choosing m , there is a mismatch between such a standard SP, and another relevant fact: a tacit assumption of this method is that all p communalities are the same. But to assume equal

communalities is usually to make a rather strong assumption, one quite possibly not supported by data in hand.

A better idea for SP entails computing the original correlation matrix, R , as well as its inverse R^{-1} . Then, denoting the *diagonal* of the inverse as D^2 (entries of which exceed unity), rescale the initial correlation matrix to DRD , and then compute eigenvalues of this rescaled correlation matrix. Since the largest entries in D^2 correspond to variables that are most predictable from all others, and vice versa, the effect is to weigh variables more if they are more predictable, less if they are less predictable from other variables in the battery. (The complement of the reciprocal of any D^2 entry is in fact the squared multiple correlation (SMC) of that variable with all others in the set.) An SP based on eigenvalues of DRD allows for variability of communalities, and is usually realistic in assuming that communalities are at least roughly proportional to SMC values.

Figure 2 provides illustrations of two scree plots based on DRD , as applied to *two simulated* random samples. Although real data were used as the starting point for each simulation, both samples are just simulation sets of (the same size as) the original data set, where four factors had consistently been identified as the ‘best’ number to interpret.

Each of these two samples yields a scree plot, and both are given in Figure 2 to provide some sense of sampling variation inherent in such data; in this case, each plot leads to breaks after four common factors – where the break is found by reading the plot from right to left. But the slope between four and five

Figure 2 Two scree plots, for two simulated data sets, each $n = 145$

factors is somewhat greater for one sample than the other, so one sample identifies m as four with slightly more clarity than the other. In fact, for some other samples examined in preparing these scree plots, breaks came after three or five factors, not just four. Note that for smaller samples greater variation can be expected in the eigenvalues, and hence the scree breaks will generally be less reliable indicators of the number of common factors for smaller samples.

So what is the principle behind the scree method? The answer is that the *variance* of the $p - m$ smallest eigenvalues is closely related to the *variance* of residual correlations associated with fitting off-diagonals of the observed correlation matrix in successive choices for m , the number of common factors. When a break occurs in the eigenvalue plot, it signifies a notable drop in the sum of squares of residual correlations after fitting the common factor model to the observed correlation matrix for a particular value of m . I have constructed a horizontal line in Figure 2 to correspond to the *mean* of the 20 smallest eigenvalues (24–4) of DRD, to help see the variation these so-called ‘*rejected*’ eigenvalues have around their mean. In general, it is the variation around such a mean of rejected eigenvalues that one seeks to reduce to a ‘reasonable’ level when choosing m in the EFA solution, since a ‘good’ EFA solution accounts well for the off-diagonals of the correlation matrix. Methods such as bootstrapping – wherein multiple versions of DRD are generated over a series of bootstrap samples of the original data matrix – can be used to get a clearer sense of sampling variation, and probably should become part of standard practice in EFA both at the level of selecting the number of factors, and assessing variation in various derived EFA results.

When covariances or correlations are well fit by some relatively small number of common factors, then scree plots often provide flexible, informative, and quite possibly persuasive evidence about the number of common factors. However, SPs alone can be misleading, and further examination of data may be helpful. The issue in selecting m vis-à-vis the SP concerns the nature or reliability of the information in **eigenvectors** associated with corresponding eigenvalues. Suppose some number m^* is seen as a possible underestimate for m ; then deciding to add one more factor to have $m^* + 1$ factors, is to decide that the additional eigenvector adds useful or meaningful structural information to the EFA solution. It is

possible that m^* is an ‘underestimate’ solely because a single correlation coefficient is poorly fit, and that adding a common factor merely reduces a single ‘large’ residual correlation. But especially if the use of $m^* + 1$ factors yields a factor loading matrix that upon rotation (see below) improves interpretability in general, there may be ex post facto evidence that m^* was indeed an underestimate. Similar reasoning may be applied when moving to $m^* + 2$ factors, etc. Note that sampling variation can also result in sample reordering of so-called *population eigenvectors* too.

An adjunct to an SP that is too rarely used is simply to plot the distribution of the residual correlations, either as a histogram, or in relation to the original correlations, for, say, m , $m + 1$, and $m + 2$ factors in the vicinity of the scree break; outliers or other anomalies in such plots can provide evidence that goes usefully beyond the SP when selecting m . Factor transformation(s) (see below) may be essential to one’s final decision. Recall that it may be a folly even to think there is a single ‘correct’ value for m for some data sets.

Were one to use a different selection of variables to compose the data matrix for analysis, or perhaps make changes in the sample (deleting or adding cases), or try various different factoring algorithms, further modifications may be expected about the number of common factors. Finally, there is always the possibility that there are simply too many distinctive dimensions of individual difference variation, that is, common factors, for the EFA method to work effectively in some situations. It is not unusual that more variables, larger samples, or generally more investigative effort, are required to resolve some basic questions such as how many factors to use in analysis.

Given some choice for m , the next decision is usually that of deciding what factoring method to use. The foregoing idea of computing DRD, finding its eigenvalues, and producing an SP based on those, can be linked directly to an EFA method called *image factor analysis* (IFA) [13], which has probably been underused, in that several studies have found it to be a generally sound and effective method. IFA is a noniterative method that produces common factor coefficients and communalities directly. IFA is based on the m largest eigenvalues, say, the diagonal entries of Γ_m , and corresponding eigenvectors, say Q_m , of the matrix denoted DRD, above. Given a particular factor method, communality estimates follow directly from selection of the number of common factors.

The analysis usually commences from a correlation matrix, so communality estimates are simply row sums of squares of the (orthogonal) factor coefficients matrix that for m common factors is computed as $\Lambda_m = D^{-1}Q_m(\Gamma_m - \phi I)^{1/2}$, where ϕ is the average of the $p - m$ smallest eigenvalues. IFA may be especially defensible for EFA when sample size is limited; more details are provided in [17], including a sensible way to modify the diagonal D^2 when the number of variables is a ‘substantial fraction’ of sample size.

A more commonly used EFA method is called *maximum likelihood factor analysis* (MLFA) for which algorithms and software are readily available, and generally well understood. The theory for this method has been studied perhaps more than any other and it tends to work effectively when the EFA problem has been well-defined and the data are ‘well-behaved.’ Specialists regularly advocate use of the MLFA method [1, 2, 16, 23], and it is often seen as the common factor method of choice when the sample is relatively large. Still, MLFA is an iterative method that can lead to poor solutions, so one must be alert in case it fails in some way. Maximum likelihood EFA methods generally call for large n ’s, using an assumption that the sample has been drawn randomly from a parent population for which multivariate normality (see **Catalogue of Probability Density Functions**) holds, at least approximately; when this assumption is violated seriously, or when sample size is not ‘large,’ MLFA may not serve its exploratory purpose well. Statistical tests may sometimes be helpful, but the sample size issue is vital if EFA is used for testing statistical hypotheses. There can be a mismatch between exploratory use of EFA and statistical testing because small samples may not be sufficiently informative to reject any factor model, while large samples may lead to rejection of every model in some domains of application. Generally scree methods for choosing the number of factors are superior to statistical testing procedures.

Given a choice of factoring methods – and of course there are many algorithms in addition to IFA and MLFA – the generation of communality estimates follows directly from the choice of m , the number of common factors. However, some EFA methods or algorithms can yield numerically unstable results, particularly if m is a substantial fraction of p , the number of variables, or when n is not large in relation to p . Choice of factor methods, like many

other methodological decisions, is often best made in consultation with an expert.

Factor Transformations to Support EFA Interpretation

Given at least a tentative choice for m , EFA methods such as IFA or MLFA can be used straightforwardly to produce matrices of factor coefficients to account for structural relations among variables. However, attempts to interpret factor coefficient matrices without further efforts to transform factors usually fall short unless $m = 1$ or 2 , as in our illustration. For larger values of m , factor transformation can bring order out of apparent chaos, with the understanding that order can take many forms. Factor transformation algorithms normally take one of three forms: Procrustes fitting to a prespecified target (see **Procrustes Analysis**), orthogonal simple structure, or oblique simple structure. All modern methods entail use of specialized algorithms. I shall begin with Procrustean methods and review each class of methods briefly.

Procrustean methods owe their name to a figure of ancient Greek mythology, Procrustes, who made a practice of robbing highway travelers, tying them up, and stretching them, or cutting off their feet to make them fit a rigid iron bed. In the context of EFA, Procrustes methods are more benign; they merely invite the investigator to prespecify his or her beliefs about structural relations among variables in the form of a target matrix, and then transform an initial factor coefficients matrix to put it in relatively close conformance with the target. Prespecification of configurations of points in m -space, preferably on the basis of hypothesized structural relations that are meaningful to the investigator, is a wise step for most EFAs even if Procrustes methods are not to be used explicitly for transformations. This is because explication of beliefs about structures can afford (one or more) reference system(s) for interpretation of empirical data structures however they were initially derived. It is a long-respected principle that prior information, specified independently of extant empirical data, generally helps to support scientific interpretations of many kinds, and EFA should be no exception. In recent times, however, methods such as confirmatory factor analysis (CFA), are usually seen as making Procrustean EFA methods obsolete because CFA methods offer generally more

sophisticated numerical and statistical machinery to aid analyses. Still, as a matter of principle, it is useful to recognize that general methodology of EFA has for over sixty years permitted, and in some respects encouraged, incorporation of sharp prior questions in structural analyses.

Orthogonal rotation algorithms provide relatively simple ways for transforming factors and these have been available for nearly forty years. Most commonly, an ‘orthomax’ criterion is optimized, using methods that have been dubbed ‘quartimax’, ‘varimax’, or ‘equamax.’ Dispensing with quotations, we merely note that in general, equamax solutions tend to produce simple structure solutions for which different factors account for nearly equal amounts of common variance; quartimax, contrastingly, typically generates one broad or general factor followed by $m - 1$ ‘smaller’ ones; varimax produces results intermediate between these extremes. The last, varimax, is the most used of the orthogonal simple structure rotations, but choice of a solution should not be based too strongly on generic popularity, as particular features of a data set can make other methods more effective. Orthogonal solutions offer the appealing feature that squared common factor coefficients show directly how much of each variable’s common variance is associated with each factor. This property is lost when factors are transformed obliquely. Also, the factor coefficients matrix alone is sufficient to interpret orthogonal factors; not so when derived factors are mutually correlated. Still, forcing factors to be uncorrelated can be a weakness when the constraint of orthogonality limits factor coefficient configurations unrealistically, and this is a common occurrence when several factors are under study.

Oblique transformation methods allow factors to be mutually correlated. For this reason, they are more complex and have a more complicated history. A problem for many years was that by allowing factors to be correlated, oblique transformation methods often allowed the m -factor space to collapse; successful methods avoided this unsatisfactory situation while tending to work well for wide varieties of data. While no methods are entirely acceptable by these standards, several, notably those of Jennrich and Sampson (direct quartimin) [12], Harris and Kaiser (obliquimax), Rozeboom (Hyball) [18], Yates (geomin) [25], and Hendrikson and White (promax) [9] are especially worthy of consideration for

applications. Browne [2], in a recent overview of analytic rotation methods for EFA, stated that Jennrich and Sampson [12] ‘solved’ the problems of oblique rotation; however, he went on to note that ‘... we are not at a point where we can rely on mechanical exploratory rotation by a computer program if the complexity of most variables is not close to one [2, p. 145].’ Methods such as Hyball [19] facilitate random starting positions in m -space of transformation algorithms to produce multiple solutions that can then be compared for interpretability. The promax method is notable not only because it often works well, but also because it combines elements of Procrustean logic with analytical orthogonal transformations. Yates’ geomin [25] is also a particularly attractive method in that the author went back to Thurstone’s basic ideas for achieving simple structure and developed ways for them to be played out in modern EFA applications. A special reason to favor simple structure transformations is provided in [10, 11] where the author noted that standard errors of factor loadings will often be substantially smaller when population structures are simple than when they are not; of course this calls attention to the design of the battery of variables.

Estimation of Factor Scores

It was noted earlier that latent variables, that is, common factors, are basic to any EFA model. A strong distinction is made between observable variables and the underlying latent variables seen in EFA as accounting for manifest correlations or covariances between all pairs of manifest variables. The latent variables are by definition never observed or observable in a real data analysis, and this is not related to the fact that we ordinarily see our data as a sample (of cases, or rows); latent variables are in principle not observable, either for statistically defined samples, or for their population counterparts. Nevertheless, it is not difficult to *estimate* the postulated latent variables, using linear combinations of the observed data. Indeed, many different kinds of factor score estimates have been devised over the years (*see Factor Score Estimation*).

Most methods for estimating factor scores are not worth mentioning because of one or another kind of technical weakness. But there are two methods that are worthy of consideration for practical applications in EFA where factor score estimates seem

needed. These are called *regression estimates* and *Bartlett* (also, *maximum likelihood*) *estimates* of factor scores, and both are easily computed in the context of IFA. Recalling that D^2 was defined as the diagonal of the inverse of the correlation matrix, now suppose the initial data matrix has been centered and scaled as Z where $Z'Z = R$; then, using the notation given earlier in the discussion of IFA, Bartlett estimates of factor scores can be computed as $X_{m-\text{Bartlett}} = Z D Q_m (\Gamma_m - \phi I)^{-1/2}$. The discerning reader may recognize that these factor scores estimates can be further simplified using the singular value decomposition of matrix $Z D$; indeed, these score estimates are just rescaled versions of the first m principal components of $Z D$. Regression estimates, in turn, are further column rescalings of the same m columns in $X_{m-\text{Bartlett}}$. MLFA factor score estimates are easily computed, but to discuss them goes beyond our scope; see [15]. Rotated or transformed versions of factor score estimates are also not complicated; the reader can go to **factor score estimation (FSE)** for details.

EFA in Practice: Some Guidelines and Resources

Software packages such as CEFA [3], which implements MLFA as well as geomin among other methods, and Hyball [18], can be downloaded from the web without cost, and they facilitate use of most of the methods for factor extraction as well as factor transformation. These packages are based on modern methods, they are comprehensive, and they tend to offer advantages that most commercial software for EFA do not. What these methods lack, to some extent, is mechanisms to facilitate modern graphical displays. Splus and R software, the latter of which is also freely available from the web [r-project.org], provide excellent modern graphical methods as well as a number of functions to implement many of the methods available in CEFA, and several in Hyball. A small function for IFA is provided at the end of this article; it works in both R and Splus. In general, however, no one source provides all methods, mechanisms, and management capabilities for a fully operational EFA system – nor should this be expected since what one specialist means by ‘fully operational’ necessarily differs from that of others.

Nearly all real-life applications of EFA require decisions bearing on how and how many cases are

selected, how variables are to be selected and transformed to help ensure approximate linearity between variates; next, choices about factoring algorithms or methods, the number(s) of common factors and factor transformation methods must be made. That there be no notably weak links in this chain is important if an EFA project is to be most informative. Virtually all questions are contextually bound, but the literature of EFA can provide guidance at every step.

Major references on EFA application, such as that of Carroll [4], point up many of the possibilities and a perspective on related issues. Carroll suggests that special value can come from side-by-side analyses of the same data using EFA methods and those based on structural equation modeling (SEM). McDonald [15] discusses EFA methods in relation to SEM. Several authors have made connections between EFA and other multivariate methods such as basic regression; see [14, 17] for examples.

Factor Analysis: Multiple Groups

Factor Analysis: Multiple Groups with Means

The confirmatory factor analysis (CFA) (*see* **Factor Analysis: Confirmatory**) model is a very effective approach to modeling multivariate relationships across multiple groups. The CFA approach to factorial invariance has its antecedents in exploratory factor analysis. **Cattell** [4] developed a set of principles by which to judge the rotated solutions from two populations with the goal being simultaneous simple structure. Further advancements were made by Horst & Schaie [7] and culminated with work by Meredith [13] in which he gave methods for rotating solutions from different populations to achieve one best fitting factor pattern. Confirmatory factor analytic techniques have made exploratory methods of testing for invariance obsolete by allowing an exact structure to be hypothesized. The multiple-group CFA approach is particularly useful when making cross-group comparisons because it allows for (a) simultaneous estimation of all parameters (including mean-level information) for all groups and (b) direct statistical comparisons of the estimated parameters across the groups. The theoretical basis for selecting groups can vary from nominal variables such as gender, race, clinical treatment group, or nationality to continuous variables that can be easily categorized such as age-group or grade level. When making comparisons across distinct groups, however, it is critical to determine that the constructs of interest have the same meaning in each group (i.e., they are said to be measurement equivalent, or have strong factorial invariance; see below). This condition is necessary in order to make meaningful comparisons across groups [1].

In order to determine measurement equivalence, the analyses should go beyond the standard covariance structures information of the traditional CFA model to also include the mean structure information [9, 14, 16, 21]. We refer to such integrated modeling as mean and covariance structure (MACS) modeling. MACS analyses are well suited to establish construct comparability (i.e., factorial

invariance) and, at the same time, detect possible between-group differences because they allow: (a) simultaneous model fitting of an hypothesized factorial structure in two or more groups (i.e., the expected pattern of indicator-to-construct relations *for both the intercepts and factor loadings*), (b) tests of the cross-group equivalence of *both intercepts and loadings*, (c) corrections for measurement error whereby estimates of the latent constructs' means and covariances are disattenuated (i.e., estimated as true and reliable values), and (d) strong tests of substantive hypotheses about possible cross-group differences on the constructs [11, 14].

The General Factor Model. To understand the logic and steps involved in multiple-group MACS modeling, we begin with the matrix algebra notations for the general factor model, which, for multiple populations $g = 1, 2, \dots, G$, is represented by:

$$X_g = \tau_g + \Lambda_g \xi_g + \delta_g \quad (1)$$

$$E(X_g) = \mu_{xg} = \tau_g + \Lambda_g \kappa_g \quad (2)$$

$$\Sigma_g = \Lambda_g \Phi_g \Lambda_g' + \Theta_g \quad (3)$$

where x is a vector of observed or manifest indicators, ξ is a vector of latent constructs, τ is a vector of intercepts of the manifest indicators, Λ is the factor pattern or loading matrix of the indicators, κ represents the means of the latent constructs, Φ is the variance-covariance matrix of the latent constructs, and Θ is a symmetric matrix with the variances of the error term, δ , along the diagonal and possible covariances among the residuals in the off diagonal. All of the parameter matrices are subscripted with a g to indicate that the parameters may take different values in each population. For the common factor model, we assume that the indicators (i.e., items, parcels, scales, responses, etc.) are continuous variables that are multivariate normal (*see Catalogue of Probability Density Functions*) in the population and the elements of Θ have a mean of zero and are independent of the estimated elements in the other parameter matrices.

In a MACS framework, there are six types of parameter estimate that can be evaluated for equivalence across groups. The first three components refer to the measurement level: (a) Λ , the unstandardized regression coefficients of the indicators on the latent constructs (the loadings of the indicators), (b) τ , the

2 Factor Analysis: Multiple Groups

intercepts or means of the indicators, and (c) Θ , the residual variances of each indicator, which is the aggregate of the unique factor variance and the unreliable variance of an indicator. The other three types of parameter refer to the latent construct level: (d) κ , the mean of the latent constructs, (e) ϕ_{ii} latent variances, and (f) ϕ_{ij} latent covariances or correlations [9, 12, 14].

Taxonomy of Invariance

A key aspect of multiple-group MACS modeling is the ability to assess the degree of factorial invariance of the constructs across groups. Factorial invariance addresses whether the constructs' measurement properties (i.e., the intercepts and loadings, which reflect the reliable components of the measurement space) are the same in two or more populations. This question is distinct from whether the latent aspects of the constructs are the same (e.g., the constructs' mean levels or covariances). This latter question deals with particular substantive hypotheses about possible group differences on the constructs (i.e., the reliable and true properties of the constructs). The concept of invariance is typically thought of and described as a hierarchical sequence of invariance starting with the weakest form and working up to the strictest form. Although we will often discuss the modeling procedures in terms of two groups, the extension to three or more groups is straightforward (see e.g., [9]).

Configural Invariance. The most basic form of factorial invariance is ensuring that the groups have the same basic factor structure. The groups should have the same number of latent constructs, the same number of manifest indicators, and the same pattern of fixed and freed (i.e., estimated) parameters. If these conditions are met, the groups are said to have configural invariance. As the weakest form of invariance, configural invariance only requires the same pattern of fixed and freed estimates among the manifest and latent variables, but does not require the coefficients be equal across groups.

Weak Factorial Invariance. Although termed 'weak factorial invariance', this level of invariance is more restricted than configural invariance. Specifically, in addition to the requirement of having the same pattern of fixed and freed parameters across groups, the

loadings are equated across groups. The manifest means and residual variances are free to vary. This condition is also referred to as pattern invariance [15] or metric invariance [6]. Because the factor variances are free to vary across groups, the factor loadings are, technically speaking, proportionally equivalent (i.e., weighted by the differences in latent variances). If weak factorial invariance is found to be untenable (see 'testing' below) then only configural invariance holds across groups. Under this condition, one has little basis to suppose that the constructs are the same in each group and systematic comparisons of the constructs would be difficult to justify. If invariance of the loadings holds then one has a weak empirical basis to consider the constructs to be equivalent and would allow cross-group comparisons of the latent variances and covariances, but not the latent means.

Strong Factorial Invariance. As Meredith [14] compellingly argued, any test of factorial invariance *should* include the manifest means – weak factorial invariance is not a complete test of invariance. With strong factorial invariance, the loadings and the intercepts are equated (and like the variances of the constructs, the latent means are allowed to vary in the second and all subsequent groups). This strong form of factorial invariance, also referred to as scalar invariance [22], is required in order for individuals with the same ability in separate groups to have the same score on the instrument. With any less stringent condition, two individuals with the same true level of ability would not have the same expected value on the measure. This circumstance would be problematic because, for example, when comparing groups based on gender on a measure of mathematical ability one would want to ensure that a male and a female with the same level of ability would receive the same score.

An important advantage of strong factorial invariance is that it establishes the measurement equivalence (or construct comparability) of the measures. In this case, constructs are defined in precisely the same operational manner in each group; as a result, they can be compared meaningfully and with quantitative precision. Measurement equivalence indicates that (a) the constructs are generalizable entities in each subpopulation, (b) sources of bias and error (e.g., cultural bias, translation errors, varying conditions of administration) are minimal, (c) subgroup differences

have not differentially affected the constructs underlying measurement characteristics (i.e., constructs are comparable because the indicators' specific variances are independent of cultural influences after conditioning on the construct-defining common variance; [14]), and (d) between-group differences in the constructs' mean, variance, and covariance relations are quantitative in nature (i.e., the nature of group differences can be assessed as mean-level, variance, and covariance or correlational effects) at the construct level. In other words, with strong factorial invariance, the broadest spectrum of hypotheses about the primary construct moments (means, variances, covariances, correlations) can be tested while simultaneously establishing measurement equivalence (i.e., two constructs can demonstrate different latent relations across subgroups, yet still be defined equivalently at the measurement level).

Strict Factorial Invariance. With strict factorial invariance, all conditions are the same as for strong invariance but, in addition, the residual variances are equated across groups. This level of invariance is not required for making veridical cross-group comparisons because the residuals are where the aggregate of the true measurement error variance and the indicator-specific variance is represented. Here, the factors that influence unreliability are not typically expected to operate in an equivalent manner across the subgroups of interest. In addition, the residuals reflect the unique factors of the measured indicators (i.e., variance that is reliable but unique to the particular indicator). If the unique factors differ trivially with regard to subgroup influences, this violation of selection theorem [14] can be effectively tolerated, if sufficiently small, by allowing the residuals to vary across the subgroups. In other words, strong factorial invariance is less biasing than strict factorial invariance because, even though the degree of random error may be quite similar across groups, if it is not exactly equal, the nonequal portions of the random error are forced into other parameters of a given model, thereby introducing potential sources of bias. Moreover, in practical applications of cross-group research such as cross-cultural studies, some systematic bias (e.g., translation bias) may influence the reliable component of a given residual. Assuming these sources of bias and error are negligible (see 'testing' below), they could be represented as unconstrained residual variance terms across groups in order to examine

the theoretically meaningful common-variance components as unbiasedly as possible.

Partial Invariance. Widaman and Reise [23] and others have also introduced the concept of partial invariance, which is the condition when a constraint of invariance is not warranted for one or a few of the loading parameters. When invariance is untenable, one may then attempt to determine which indicators contribute significantly to the misfit ([3] [5]). It is likely that only a few of the indicators deviate significantly across groups, giving rise to the condition known as partial invariance. When partial invariance is discovered there are a variety of ways to proceed. (a) One can leave the estimate in the model, but not constrain it to be invariant across groups and argue that the invariant indicators are sufficient to establish comparability of the constructs [23]; (b) one can argue that the differences between indicators are small enough that they would not make a substantive difference and proceed with invariance constraints in place [9]; (c) one could decide to reduce the number of indicators by only using indicators that are invariant across groups [16]; (d) one could conclude that because invariance cannot be attained that the instrument must be measuring different constructs across the multiple groups and, therefore, not use the instrument at all [16]. Milsap and Kwok [16] also describe a method to assess the severity of the violations of invariance by evaluating the sensitivity and specificity at various selection points.

Selection Theorem Basis for Expecting Invariance. The loadings and intercepts of a constructs indicators can be expected to be invariant across groups under a basic tenet of selection theorem – namely, conditional independence ([8, 14]; see also [18]). In particular, if subpopulation influences (i.e., the basis for selecting the groups) and the *specific* components (unique factors) of the construct's manifest indicators are independent when conditioned on the common construct components, then an invariant measurement space can be specified even under extreme selection conditions. When conditional independence between the indicators' unique factors and the selection basis hold, the construct information (i.e., common variance) contains, or carries, information about subpopulation influences. This expectation is quite reasonable if one assumes that the subpopulations derive from a common population from which the subpopulations can be described as 'selected' on the basis of one or

more criteria (e.g., experimental treatment, economic affluence, degree of industrialization, degree of individualism etc.). This expectation is also reasonable if one assumes on the basis of a specific theoretical view that the constructs should exist in each assessed subpopulation and that the constructs' indicators reflect generally equivalent domain representations.

Because manifest indicators reflect both common and specific sources of variance, cross-group effects may influence not only the common construct-related variance of a set of indicators but also the specific variance of one or more of them [17]. Measurement equivalence will hold if these effects have influenced only the common-variance components of a set of construct indicators and not their unique-specific components [8, 14, 18]. If cross-group influences differentially and strongly affect the specific components of indicators, nonequivalence would emerge. Although measurement nonequivalence can be a meaningful analytic outcome, it disallows, when sufficiently strong, quantitative construct comparisons.

Identification Constraints

There are three methods of placing constraints on the model parameters in order to identify the constructs and model (*see Identification*). When a mean structure is used, the location must be identified in addition to the scale of the other estimated parameters.

The first method to identification and scale setting is to fix a parameter in the latent model. For example, to set the scale for the location parameters, one can fix the latent factor mean, κ , to zero (or a nonzero value). Similarly, to set the scale for the variance-covariance and loading parameters one can fix the variances, ϕ_{ii} to 1.0 (or any other nonzero value). The advantages of this approach are that the estimated latent means in each subsequent group are relative mean differences from the first group. Because this first group is fixed at zero, the significance of the latent mean estimates in the subsequent groups is the significance of the difference from the first group. Fixing the latent variances to 1.0 has the advantage of providing estimates of the associations among the latent constructs in correlational metric as opposed to an arbitrary covariance metric.

The second common method is known as the marker-variable method. To set the location parameters, one element of τ is set to zero (or a nonzero

value) for each construct. To set the scale, one element of λ is fixed to 1.0 (or any other nonzero value) for each construct. This method of identification is less desirable than the 1st and 3rd methods because the location and scale of the latent construct is determined arbitrarily on the basis of which indicator is chosen. Reise, Widaman, and Pugh [19] recommend that if one chooses this approach the marker variables should be supported by previous research or selected on the basis of strong theory.

A third possible identification method is to constrain the sum of τ for each factor to zero [20]. For the scale identification, the λ s for a factor should sum to p , the number of manifest variables. This method forces the mean and variance of the latent construct to be the weighted average of all of its indicators' means and loadings. The method has the advantage of providing a nonarbitrary scale that can legitimately vary across constructs and groups. It would be feasible, in fact, to compare the differences in means of two different constructs if one was theoretically motivated to do so (see [20], for more details of this method).

Testing for Measurement Invariance and Latent Construct Differences

In conducting cross-group tests of equality, either a statistical or a modeling rationale can be used for evaluating the tenability of the cross-group restrictions [9]. With a statistical rationale, an equivalence test is conducted as a nested-model comparison between a model in which specific parameters are constrained to equality across groups and one in which these parameters (and all others) are freely estimated in all groups. The difference in χ^2 between the two models is a test of the equality restrictions (with degrees of freedom equal to the difference in their degrees of freedom). If the test is nonsignificant then the statistical evidence indicates no cross-group differences between the equated parameters. If it is significant, then evidence of cross-group inequality exists.

The other rationale is termed a *modeling rationale* [9]. Here, model constraints are evaluated using practical fit indices to determine the overall adequacy of a fitted model. This rationale is used for large models with numerous constrained parameters because the χ^2 statistic is an overly sensitive index of model fit, particularly for large numbers of constraints and when estimated on large sample sizes (e.g., [10]).

From this viewpoint, if a model with *numerous* constraints evinces adequate levels of practical fit, then the *set* of constraints are reasonable approximations of the data.

Both rationales could be used in testing the *measurement level* and the *latent level* parameters. Because these two levels represent distinctly and qualitatively different empirical and theoretical goals, however, their corresponding rationale could also be different. Specifically, testing measurement equivalence involves evaluating the general tenability of an imposed indicator-to-construct structure via overall model fit indices. Here, various sources of model misfit (random or systematic) may be deemed substantively trivial if model fit is acceptable (i.e., if the model provides a reasonable approximation of the data; [2, 9]). The conglomerate effects of these sources of misfit, when sufficiently small, can be depicted parsimoniously as residual variances and general lack of fit, with little or no loss to theoretical meaningfulness (i.e., the trade-off between empirical accuracy and theoretical parsimony; [11]). When compared to a non-invariance model, an invariance model differs substantially in interpretability and parsimony (i.e., fewer parameter estimates than a non-invariance model), and it provides the theoretical and mathematical basis for quantitative between-group comparisons.

In contrast to the measurement level, the latent level reflects interpretable, error-free effects among constructs. Here, testing them for evidence of systematic differences (i.e., the hypothesis-testing phase of an analysis) is probably best done using a statistical rationale because it is a precise criteria for testing the specific theoretically driven questions about the constructs and because such substantive tests are typically narrower in scope (i.e., fewer parameters are involved). However, such tests should carefully consider issues such as error rate and effect size.

Numerous examples of the application of MACS modeling can be found in the literature, however, Little [9] offers a detailed didactic discussion of the issues and steps involved when making cross-group comparisons (including the LISREL source code used to estimate the models and a detailed Figural representation). His data came from a cross-cultural study of personal agency beliefs about school performance that included 2493 boys and girls from Los Angeles, Moscow, Berlin, and Prague. Little conducted an 8-group MACS comparison of boys and girls across the

four sociocultural settings. His analyses demonstrated that the constructs were measurement equivalent (i.e., had strong factorial invariance) across all groups indicating that the translation process did not unduly influence the measurement properties of the instrument. However, the constructs themselves revealed a number of theoretically meaningful differences, including striking differences in the mean levels and the variances across the groups, but no differences in the strength of association between the two primary constructs examined.

Extensions to Longitudinal MACS Modeling

The issues related to cross-group comparisons with MACS models are directly applicable to longitudinal MACS modeling. That is, establishing the measurement equivalence (strong metric invariance) of a construct's indicators over time is just as important as establishing their equivalence across subgroups. One additional component of longitudinal MACS modeling that needs to be addressed is the fact that the specific variances of the indicators of a construct will have some degree of association across time. Here, independence of the residuals is not assumed, but rather dependence of the unique factors is expected. In this regard, the *a priori* factor model, when fit across time, would specify and estimate all possible residual correlations of an indicator with itself across each measurement occasion.

Summary

MACS models are a powerful tool for cross-group and longitudinal comparisons. Because the means or intercepts of measured indicators are included explicitly in MACS models, they provide a very strong test of the validity of construct comparisons (i.e., measurement equivalence). Moreover, the form of the group- or time-related differences can be tested on many aspects of the constructs (i.e., means, variances, and covariances or correlations). As outlined here, the tenability of measurement equivalence (i.e., construct comparability) can be tested using model fit indices (i.e., the modeling rationale), whereas specific hypotheses about the nature of possible group differences on the constructs can be tested using precise statistical criteria. A measurement equivalent model is advantageous for three reasons: (a) it is theoretically very parsimonious and, thus, a reasonable *a*

priori hypothesis to entertain, (b) it is empirically very parsimonious, requiring fewer estimates than a non-invariance model, and (c) it provides the mathematical and theoretical basis by which quantitative cross-group or cross-time comparisons can be conducted. In other words, strong factorial invariance indicates that constructs are fundamentally similar in each group or across time (i.e., comparable) and hypotheses about the nature of possible group- or time-related influences can be meaningfully tested on any of the constructs' basic moments across time or across each group whether the groups are defined on the basis of culture, gender, or any other grouping criteria.

Factor Analysis: Multitrait–Multimethod

The Multitrait–Multimethod Matrix

The well-known paper by Campbell and Fiske [6] proposed the multitrait–multimethod (MTMM) matrix as a measurement design to study trait validity across assessment methods. Their central idea was that traits should be independent of and detectable by a variety of measurement methods. In particular, the magnitude of a trait should not change just because a different assessment method is used. Campbell and Fiske's main distinction was between two forms of validity, identified as *convergent* and *discriminant*. Convergent validity assures that measures of the same trait are statistically related to each other and that their error and unique components are relatively small. Discriminant validity postulates that measures of one trait are not too highly correlated with measures of different traits and particularly not too highly correlated just because they share the same assessment method.

The variables of an MTMM matrix follow a crossed-factorial measurement design whereby each of t traits is assessed with each of m measurement methods. Table 1 gives an example of how the observed variables and their correlation coefficients are arranged in the correlation matrix, conventionally ordering traits within methods. Because the matrix is symmetric, only entries in its lower half have been marked. Particular types of correlations are marked symbolically:

- V – validity diagonals, correlations of measures of the same traits assessed with different methods.
- M – monomethod triangles, correlations of measures of different traits that share the same methods.
- H – heterotrait–heteromethod triangles, correlations of measures of different traits obtained with different methods.
- 1 – main diagonal, usually containing unit entries. It is not uncommon to see the unit values replaced by reliability estimates.

Campbell and Fiske [6] proposed four qualitative criteria for evaluating convergent and discriminant validity by the MTMM matrix.

CF1 (convergent validity): ‘...the entries in the validity diagonal [V] should be significantly different from zero and sufficiently large ...’

CF2 (discriminant validity): ‘...a validity diagonal value [V] should be higher than the values lying in its column and row in the heterotrait–heteromethod triangles [H].’

CF3 (discriminant validity): ‘...a variable correlate higher with an independent effort to measure the same trait [V] than with measure designed to get at different traits which happen to employ the same method [M].’

CF4 (discriminant validity): ‘...the same pattern of trait interrelationship be shown in all of the heterotrait triangles of both the monomethod [M] and heteromethod [H] blocks.’

Depending on which of the criteria were satisfied, convergent or discriminant validity of assessment instruments would then be ascertained or rejected.

Confirmatory Factor Analysis Approach to MTMM

Confirmatory factor analysis (CFA) (*see Factor Analysis: Confirmatory*) was proposed as a model-oriented approach to MTMM matrix analysis by [1], [11], [12], and [13]. Among the several competing multivariate models for MTMM matrix analysis reviewed by [17] and [18], CFA is the only approach with an appreciable following in the literature.

Under the factor model (*see Factor Analysis: Exploratory*), the $n \times p$ observed data matrix $\mathbf{X}$ of n observations on p variables arises as a linear combination of $n \times k$, $k < p$ factor scores, with factor loading matrix $\mathbf{\Lambda}$, and uncorrelated residuals $\mathbf{E}$. The covariance structure of the observed data is

$$\mathbf{\Sigma}_x = \mathbf{\Lambda} \mathbf{\Phi} \mathbf{\Lambda}' + \mathbf{\Theta}, \quad (1)$$

where $\mathbf{\Phi}$ is the covariance matrix of the k latent factors and $\mathbf{\Theta}$ the diagonal covariance matrix of the residuals. There are two prominent models for MTMM factor analysis: the *trait-only* model [11, 12] expressing the observed variables in terms of t correlated trait factors and the *trait-method* factor model [1, 12, 13] with t trait and m method factors.

Confirmatory Factor Analysis – Trait-only Model

The trait-only model allows one factor per trait. Trait factors are usually permitted to correlate. For the nine-variable MTMM matrix shown in Table 1, assuming the same variable order, the loading matrix Λ_τ has the following simple structure:

$$\Lambda_\tau = \begin{pmatrix} \lambda_{1,1} & 0 & 0 \\ 0 & \lambda_{2,2} & 0 \\ 0 & 0 & \lambda_{3,3} \\ \lambda_{4,1} & 0 & 0 \\ 0 & \lambda_{5,2} & 0 \\ 0 & 0 & \lambda_{6,3} \\ \lambda_{7,1} & 0 & 0 \\ 0 & \lambda_{8,2} & 0 \\ 0 & 0 & \lambda_{9,3} \end{pmatrix}. \quad (2)$$

and the matrix of factor correlations is

$$\Phi_\tau = \begin{pmatrix} 1 & \phi_{21} & \phi_{31} \\ \phi_{21} & 1 & \phi_{32} \\ \phi_{31} & \phi_{32} & 1 \end{pmatrix}. \quad (3)$$

All zero entries in Λ_τ and the diagonal entries in Φ_τ are fixed (predetermined) parameters; the p factor loading parameters $\lambda_{i,j}$, $t(t-1)/2$ factor correlations, and p uniqueness coefficients in the diagonal of Θ are estimated from the data. The model is identified when three or more methods are included in the measurement design. For the special case that all intertrait correlations are *nonzero*, model identification requires only two methods (two-indicator rule [2]).

The worked example uses the MTMM matrix of Table 2 on the basis of data by Flamer [8], also published in [9] and [22]. The traits are *Attitude toward Discipline in Children* (ADC), *Attitude toward Mathematics* (AM), and *Attitude toward the Law* (AL). The methods are all paper-and-pencil, differing by response format: dichotomous Likert (L) scales, Thurstone (Th) scales, and the semantic differential (SD) technique. Distinctly larger entries in the validity diagonals (in bold face) and similar patterns of small off-diagonal correlations in the monomethod triangles and heterotrait–heteromethod

Table 2 Flamer (1978) attitude data, sample A ($N = 105$)^a

	ADC_L	AM_L	AL_L	ADC_Th	AM_Th	AL_Th	ADC_SD	AM_SD	AL_SD

AL		0.39	−0.05	1.0	
$\chi^2 = 23.28$					$P = 0.503$
df = 24					$N = 105$

blocks suggest some stability of the traits across the three methods.

The parameter estimates for the trait-only factor model are shown in Table 3. The solution is admissible and its low maximum-likelihood χ^2 -value signals acceptable statistical model fit. No additional model terms are called for. This factor model postulates considerable generality of traits across methods, although the large uniqueness estimates of some of the attitude measures indicate low factorial validity, limiting their practical use.

Performance of the trait-only factor model with other empirical MTMM data is mixed. In Wothke's [21] reanalyses of 23 published MTMM matrices, the model estimates were inadmissible or failed to converge in 10 cases. Statistically acceptable model fit was found with only 2 of the 23 data sets.

Confirmatory Factor Analysis – Traits Plus Methods Model

Measures may not only be correlated because they reflect the same trait but also because they share the same assessment method. Several authors [1, 12]

have therefore proposed the less restrictive *trait-method* factor model, permitting systematic variation due to shared methods as well as shared traits. The factor loading matrix of the expanded model simply has several columns of method factor loadings appended to the right, one column for each method:

$$\Lambda_{\tau\mu} = \left(\begin{array}{ccc|ccc} \lambda_{1,1} & 0 & 0 & \lambda_{1,4} & 0 & 0 \\ 0 & \lambda_{2,2} & 0 & \lambda_{2,4} & 0 & 0 \\ 0 & 0 & \lambda_{3,3} & \lambda_{3,4} & 0 & 0 \\ \lambda_{4,1} & 0 & 0 & 0 & \lambda_{4,5} & 0 \\ 0 & \lambda_{5,2} & 0 & 0 & \lambda_{5,5} & 0 \\ 0 & 0 & \lambda_{6,3} & 0 & \lambda_{6,5} & 0 \\ \lambda_{7,1} & 0 & 0 & 0 & 0 & \lambda_{7,6} \\ 0 & \lambda_{8,2} & 0 & 0 & 0 & \lambda_{8,6} \\ 0 & 0 & \lambda_{9,3} & 0 & 0 & \lambda_{9,6} \end{array} \right). \quad (4)$$

A particularly interesting form of factor correlation matrix is the block-diagonal model, which implies independence between trait and method factors:

$$\Phi_{\tau\mu} = \begin{pmatrix} \Phi_\tau & 0 \\ 0 & \Phi_\mu \end{pmatrix}. \quad (5)$$

4 Factor Analysis: Multitrait–Multimethod

In the structured correlation matrix (5), the submatrix Φ_τ contains the correlations among traits and the submatrix Φ_μ contains the correlations among methods.

While the block-diagonal trait-method model appeared attractive when first proposed, there has been growing evidence that its parameterization is inherently flawed. Inadmissible or unidentified model solutions are nearly universal with both simulated and empirical MTMM data [3, 15, 21]. In addition, identification problems of several aspects of the trait-method factor model have been demonstrated formally [10, 14, 16, 20]. For instance, consider factor loading structures whose nonzero entries are *proportional* by rows and columns:

$$\Lambda_{\tau\mu}^{(p)} = \left(\begin{array}{ccc|ccc} \lambda_1 & 0 & 0 & \lambda_4 & 0 & 0 \\ 0 & \delta_2 \cdot \lambda_2 & 0 & \delta_2 \cdot \lambda_4 & 0 & 0 \\ 0 & 0 & \delta_3 \cdot \lambda_3 & \delta_3 \cdot \lambda_4 & 0 & 0 \\ \delta_4 \cdot \lambda_1 & 0 & 0 & 0 & \delta_4 \cdot \lambda_5 & 0 \\ 0 & \delta_5 \cdot \lambda_2 & 0 & 0 & \delta_5 \cdot \lambda_5 & 0 \\ 0 & 0 & \delta_6 \cdot \lambda_3 & 0 & \delta_6 \cdot \lambda_5 & 0 \\ \delta_7 \cdot \lambda_1 & 0 & 0 & 0 & 0 & \delta_7 \cdot \lambda_6 \\ 0 & \delta_8 \cdot \lambda_2 & 0 & 0 & 0 & \delta_8 \cdot \lambda_6 \\ 0 & 0 & \delta_9 \cdot \lambda_3 & 0 & 0 & \delta_9 \cdot \lambda_6 \end{array} \right), \quad (6)$$

where the δ_i are $mt - 1$ nonzero scale parameters for the rows of $\Lambda_{\tau\mu}^{(p)}$, with $\delta_1 = 1$ fixed and all other δ_i estimated, and the λ_k are a set of $m + t$ nonzero scale parameters for the columns of $\Lambda_{\tau\mu}^{(p)}$, with all λ_k estimated. Grayson and Marsh [10] proved algebraically that factor models with loading matrix (6) and factor correlation structure (5) are unidentified no matter how many traits and methods are analyzed. Even if $\Lambda_{\tau\mu}^{(p)}$ is further constrained by setting all (row) scale parameters to unity ($\delta_i = 1$), the factor model will remain unidentified [20].

Currently, identification conditions for the general form of the trait-method model are not completely known. Identification and admissibility problems appear to be the rule with empirical MTMM data, although an identified, admissible, and fitting solution has been reported for one particular dataset [2]. However, in order to be identified, the estimated factor loadings must necessarily be different from the proportional structure in (6) – a difference that would complicate the evaluation of trait validity. Estimation itself can also be difficult: The usually iterative estimation process often approaches an intermediate solution of the form (6) and cannot

continue because the matrix of second derivatives of the fit function becomes rank deficient at that point. This is a serious practical problem because condition (6) is so general that it ‘slices’ the identified solution space into many disjoint subregions so that the model estimates can become extremely sensitive to the choice of start values. Kenny and Kashy [14] noted that ‘... estimation problems increase as the factor loadings become increasingly similar.’

There are several alternative modeling approaches that the interested reader may want to consult: (a) CFA with alternative factor correlation structures [19]; (b) CFA with correlated uniqueness coefficients [4, 14, 15]; (c) covariance components

analysis [22]; and (d) the direct product model [5]. Practical implementation issues for several of these models are reviewed in [14] and [22].

Conclusion

About thirty years of experience with confirmatory factor analysis of MTMM data have proven less than satisfactory. Trait-only factor analysis suffers from poor fit to most MTMM data, while the block-diagonal trait-method model is usually troubled by identification, convergence, or admissibility problems, or by combinations thereof. In the presence of method effects, there is no generally accepted multivariate model to yield summative measures of convergent and discriminant validity. In the absence of such a model, ‘(t)here remains the basic eyeball analysis as in the original article [6]. It is not always dependable; but it is cheap’ [7].

Factor Analysis of Personality Measures

The technique of **factor analysis** was developed about 100 years ago by **Charles Spearman** [12] who applied the technique to the observed correlations among measures of mental abilities. Briefly, factor analysis is a statistical technique that derives aggregates of variables (typically called ‘factors’) from the observed relations (typically indexed by correlations) among those variables. The result of Spearman’s analysis was the identification of a single factor that seemed to underlie observed scores on a large number of measures of human mental ability. Subsequently, further applications of factor analysis to the mental ability domain indicated that the one factor model was too simple. In particular, **Louis Thurstone** suggested seven primary mental ability factors rather than the single factor claimed by Spearman. Interestingly, Thurstone’s 1933 American Psychological Association presidential address, *Vectors of the Mind*, [13] in which he presented this alternate view of the structure of mental abilities focused as much or more on the application of factor analysis to personality data, and this represents the first presentation of a major factor analysis of personality measures. Thurstone, however, later dropped this line of investigation to focus on mental abilities.

Numerous other personality scientists soon followed Thurstone’s initial lead and began using factor analytic techniques to identify, evaluate, and refine the major dimensions of personality. The personality theories and measures of **Raymond Cattell** and Hans Eysenck represent two major early applications and more recently the factor analyses of Jack Digman, Lewis Goldberg, Paul Costa, and Jeff McCrae, and a host of others have laid the foundation for a widely used, though not by any means universally accepted, five-factor structure of personality often called the *Big Five*. Today there are a variety of structural models of personality that are based on factor analyses. A number of these are summarized in Table 1.

This table is intended to be illustrative rather than comprehensive or definitive. There are other systems, other variants on the systems shown here,

and other scientists who might be listed. More comprehensive tables can be found in [4, 9, and 10]. Although Table 1 represents only a portion of the factor analytic models of personality, it is sufficient to raise the fundamental issue that will be the focus of this contribution: Why does the same general analytic strategy (factor analysis) result in structural models of personality that are so diverse? In addressing this issue, I will consider the variety of factor analytic procedures that result from different subjective decisions about the conduct of a factor analysis. A more thorough discussion of these issues can be found in [6] and [7]. These decisions include (a) the sample of observed items to be factored, (b) the method of factor extraction, (c) the criteria for deciding the number of factors to be extracted, (d) the type of factor rotation if any, and (e) the naming of the factors. Readers who believe that science is objective and who believe that the diversity of results obtained from factor analyses is *prima facie* evidence that the technique is unscientific will find the tone of this contribution decidedly unsympathetic to that view.

What Personality Variables are to be Included in a Factor Analysis?

The first decision in any scientific study is what to study. This is an inherently subjective decision and, at its broadest level, is the reason that some of us become, say, chemists and others of us become, say, psychologists. In the more specific case of studying the structure of human personality, we must also begin with a decision of which types of variables are relevant to personality. Factor analysis, just as any other statistical technique, can only operate on the data that are presented. In the case of personality structure for example, a factor representing Extraversion will only be found if items that indicate Extraversion are present in the data: No Extroversion items; no Extroversion factor. An historical example of the influence of this decision on the study of personality structure was Cattell’s elimination of a measure of intelligence from early versions of the domains he factored. This marked the point at which a powerful individual difference variable, intelligence, disappeared from the study of personality. More recently, the decision on the part of Big Five theorists to exclude terms that are purely evaluative such as ‘nice’, or ‘evil’, from the personality domain meant that no factors representing general evaluation were

2 Factor Analysis of Personality Measures

Table 1 Illustration of the major structural models of personality based on factor analysis

Number of factors	Representative labels and structure	Associated theorists
2	Love-Hate; Dominance-Submission (interpersonal circle)	Leary, Wiggins
2	Alpha (A, C, N) Beta (E, O) (Higher order factors of the Big Five)	Digman
3	Extroversion, Neuroticism, Psychoticism	Eysenck
5	E, A, C, N, O (Big Five; Five-Factor Model)	Digman, Goldberg, Costa & McCrae
7	E, A, C, N, O + Positive and Negative Evaluation	Tellegen, Waller, Benet
16	16- PF; 16 Primary factors further grouped into five more global factors ^a	Cattell

Note: E = Extroversion, A = Agreeableness, C = Conscientiousness, N = Neuroticism, O = Openness.

^aA complete list of the labels for the 16 PF can be found in [3].

included in the structure of personality. Adding such items to the domain to be factored resulted, not surprisingly, in a model called the *Big Seven* as shown in Table 1.

Cattell's decision to exclude intelligence items or Big Five theorists' decisions to exclude purely evaluative items represent different views of what is meant by personality. It would be difficult to identify those views as correct or incorrect in any objective sense, but recognizing these different views can help clarify the differences in Table 1 and in other factor analyses of personality domains. The point is that understanding the results of a factor analysis of personality measures must begin with a careful evaluation of the measures that are included (and excluded) and the rationale behind such inclusion or exclusion. Probably the most prominent rationale for selecting variables for a factor analysis in personality has been the 'lexical hypothesis'. This hypothesis roughly states that all of the most important ways that people differ from each other in personality will become encoded in the natural language as single word person descriptive terms such as 'friendly' or 'dependable'. On the basis of this hypothesis, one selects words from a list of all possible terms that describe people culled from a dictionary and then uses those words as stimuli for which people are asked to describe themselves or others on those terms. Cattell used such a list that was compiled by Allport and Odbert [1] in his analyses, and more recently, the Big Five was based on a similar and more recent list compiled by Warren Norman [11].

How (and Why) Should Personality Factors be Extracted? The basic data used in a factor analysis

of personality items are responses (typically ratings of descriptiveness of the item about one's self or possibly another person) from N subjects to k personality items; for example, 'talks to strangers', 'is punctual', or 'relaxed'. These $N \times k$ responses are then converted into a $k \times k$ correlation (or less often a covariance) matrix, and the $k \times k$ matrix is then factor analyzed to yield a factor matrix showing the 'loadings' of the k variables on the m factors. Specifically, factor analysis operates on the common (shared) variance of the variables as measured by their intercorrelations. The amount of variance a variable shares with the other variables is called the *variables communality*. Factor analysis proceeds by extracting factors iteratively such that the first factor accounts for as much of the total common variance across the items (called the *factor's eigenvalue*) as possible, the second factor accounts for as much of the remaining common variance as possible and so on. Figure 1 shows a heuristic factor matrix. The elements of the matrix are the estimated correlations between each variable and each factor. These correlations are called 'loadings'. To the right of the matrix is a column containing the final communality estimates (usually symbolized as h^2). These are simply the sum of the squared loadings for each variable across the m factors and thus represent the total common variance in each variable that is accounted for by the factors. At the bottom of the matrix are the eigenvalues of the factors. These are the sum of the squared loadings for each factor across the k variables and thus represent the total amount of variance accounted for by each factor.

The point at which the correlation matrix is converted to a factor matrix represents the next

Figure 1 Heuristic representation of a factor matrix

crucial subjective decision point in the factor analysis. Although the communalities of the variables can be calculated from the final factor matrix, these communalities must be initially estimated for the factor analysis to proceed and the investigator must decide how those initial communality values are to be estimated. The vast majority of factor analyses are based on one of two possible decisions about these estimates. In principle, these decisions reflect the investigators belief about the nature of factors and the goal of the factor analysis. One reason for extracting factors from a matrix of correlations is simply as an aid to interpreting the complex patterns implied by those correlations. The importance of this aid can be readily appreciated by anyone who has tried to discern how groups of variables are similar and different on the basis of the 4950 unique correlations available from a set of 100 items, or, less ambitiously, among the 435 unique correlations available from a set of 30 items or measures. This 'orderly simplification' of a correlation matrix as a goal of factor analysis has been attributed to Cyril Burt, among others.

A second reason for extracting factors is perhaps more profound. This reason is to discover the underlying factors that 'cause' individuals to respond to the items in certain ways. This view of factors as 'causes', is, of course, more controversial because of the 'correlations do not imply causation' rule. However, this rule should not blind us to the fact that relations among variables are caused by something;

it is just that we do not necessarily know what that cause is on the basis of correlations alone.

The difference between this descriptive and explanatory view of factor analysis is the foundation of the two major approaches to factor extraction; **principal component analysis (PC)** and principle axis factor analysis (PF) (*see Factor Analysis: Exploratory*). Figure 2 illustrates the difference between these two approaches using structural model diagrams. As can be seen in Figures 2(a) and 2(b) the difference between PC and PF is the direction of the arrows in the diagram. Conceptually, the direction of the arrows indicates the descriptive emphasis of PC analysis and the causal emphasis of PF analysis. In PC analysis the items together serve to 'define' the component and it serves to summarize the items that define it. In PF analysis the underlying factor serves as a cause of why people respond consistently to a set of items. The similarity of the items, the responses to which are caused by the factor, is used to label the cause, which could be biological, conditioned, or cognitive.

Because correlations are bidirectional, the direction of the arrows in a path diagram is statistically arbitrary and both diagrams will be equally supported by the same correlation matrix. However, there is a crucial additional difference between Figures 2(a) and 2(b) that does lead to different results between PC and PF. This difference is shown in Figure 1(c), which adds error terms to the item responses when they are viewed as 'caused' by the factor in PF analysis. The addition of error in PF analysis recognizes that the response to items is not perfectly predicted by the underlying factor. That is, there is some 'uniqueness' or 'error' in individuals' responses in addition to the common influence of the factor. In PC analysis, no error is assigned to the item responses as they are not viewed as caused by the factor. It is at this point that the statistical consequence of these views becomes apparent. In PC analysis, the initial communality estimates for the item are all fixed at 1.0 as all of the variance is assumed to be common. In PF analysis, the initial communality estimates are generally less than 1.0 (see next paragraph) to reflect that some of the item variance is unique. The consequence of recognizing that some of the variability in people's responses to items is unique to that item is to reduce the amount of variance that can be 'explained' or attributed to the factors. Thus, PF analysis typically

4 Factor Analysis of Personality Measures

Figure 2 Path diagram Illustrating the difference between PC and PF

results in factors that account for less variance than PC analysis.

There is also a computational consequence of choosing PF over PC analysis. PF analysis is much more difficult from a computational standpoint than PC because one needs to estimate the error or uniqueness of the items before the analysis can proceed. This is typically done by regressing each item on all the others in the set to be factored, and using the resulting R^2 as the estimate of the items common variance (communality) and $1 - R^2$ as the items unique variance. **Multiple linear regression** requires inverting a correlation matrix, a time consuming, tedious, and error-prone task. If one were to factor, say, 100 items one would have to invert 100 matrices. This task would simply be beyond the skills and temperament of most investigators and as a consequence the vast majority of historical factor analyses used the PC approach, which requires no matrix inversion. Today we have computers, which, among other things are designed for time consuming, tedious, and error-prone tasks, so the computational advantage of PC is no longer of much relevance. However, the conservative nature of science, which tends to foster continuity of methods and measures, has resulted in the vast majority of factor analyses of personality items to continue to be based on PC, regardless of the (often unstated) view of investigator about the nature of factors or the goal of the analysis.

Within the domain of personality it is often the case that similar factor structures emerge from the same data regardless of whether PC or PF is employed, probably because the initial regression-based communality estimates for personality variables in PF tend to approach the 1.0 estimates used by PC analysis. Thus, the decision to use PC or PF on personality data may be of little practical consequence. However, the implied view of factors as descriptive or causal by PC or PF respectively still has important implications for the study of personality. The causal view of factors must be a disciplined view to avoid circularity. For example, it is easy to 'explain' that a person has responded in an agreeable manner because they are high on the agreeableness factor. Without further specifying, and independently testing, the source of that factor (e.g., genetic, cognitive, environmental), the causal assertion is circular ('He is agreeable because he is agreeable') and untestable. The PC view avoids this problem by simply using the factor descriptively without implying a cause.

However, the 'merely' descriptive view of factors is scientifically less powerful and two of the earliest and most influential factor analytic models of personality of Cattell [3] and Eysenck [5] both viewed factors as causal. Eysenck based his three factors on a strong biological theory that included the role of individual differences in brain structure and systems of biological activation and inhibition as the basis

of personality, and Eysenck used factor analysis to evaluate his theory by seeing if factors consistent with his theory could be derived from personality ratings. Cattell, on the other hand, did not base his 16 factors on an explicit theory but instead viewed factor analysis as a tool for empirically discovering the important and replicable factors that caused personality. The widely accepted contemporary model of five factors also has both descriptive and causal interpretations. The term 'Five-Factor Model' used by Costa and McCrae among others emphasizes a causal interpretation, whereas the term 'Big Five' used by Goldberg among others emphasizes the descriptive view.

How Many Factors are There? Probably the most difficult issue in factor analysis is deciding on the number of factors. Within the domain of personality, we have seen that the number of factors extracted is influenced crucially by the decision of how many and what type of items to factor. However, another reason that different investigators may report different numbers of factors is that there is no single criterion for deciding how many factors are needed or useful to account for the common variance among a set of items. The problem is that as one extracts more factors one necessarily accounts for more common variance. Indeed in PC analysis one can extract as many factors as there are items in the data set and in doing so one can account for all the variance. Thus, the decision about the number of factors to extract is ultimately based on the balance between the statistical goal of accounting for variance and the substantive goal of simplifying a set of data into a smaller number of *meaningful* descriptive components or underlying causal factors. The term 'meaningful' is the source of the inherent subjectivity in this decision

The most common objective criteria that has been used to decide on the number of factors is Kaiser's 'eigenvalues greater than 1.0' rule. The logic of this rule is that, at a minimum, a factor should account for more common variance than any single item. On the basis of this logic, it is clear that this rule only applies to PC analysis where the common variance of an item is set at 1.0 and indeed Kaiser proposed this rule for PC analysis. Nonetheless, one often sees this rule misapplied in PF analyses. Although there is a statistical objectivity about this rule, in practice its application often results in factors

that are specific to only one or two items and/or factors that are substantively difficult to interpret or name.

One recent development that addresses the number of factors problem is the use of factor analyses based on maximum-likelihood criteria. In principle, this provides a statistical test of the 'significance' of the amount of additional variance accounted for by each additional factor. One then keeps extracting factors until the additional variance accounted for by each factor does not significantly increase over the variance accounted for by the previous factor. However, it is still often the case that factors that account for 'significantly' more variance do not include large numbers of items and/or are not particularly meaningful. Thus, the tension between statistical significance and substantive significance remains, and ultimately the number of factors reported reflects a subjective balance between these two criteria.

How Should the Factors be Arranged (Rotated)?

Yet another source of subjectivity in factor analysis results because the initial extraction of factors does not provide a statistically unique set of factors. Statistically, factors are extracted to account for as much variance as possible. However, once a set of factors is extracted, it turns out that there are many different combinations of factors and item loadings that will account for exactly the same amount of total variance of each item. From a statistical standpoint, as long as a group of factors accounts for the same amount of total variance, there is no basis for choosing one group over another. Thus, investigators are free to select whatever arrangements of factors and item loadings they wish. The term that is used to describe the rearrangement of factors among a set of personality items is 'rotation', which comes from the geometric view of factors as vectors moving (rotating) through a space defined by items.

There is a generally accepted criterion, called *simple structure*, that is used to decide how to rotate factors. An ideal simple structure is one where each item correlates 1.0 with one factor and 0.00 with the other factors. In actual data this ideal will not be realized, but the goal is to come as close to this ideal as possible for as many items as possible. The rationale for simple structure is simplicity and this rationale holds for both PC and PF analyses. For PC analysis, simple

structure results in a description of the relations among the variables that is easy to interpret because there is little item overlap between factors. For PF analysis the rationale is that scientific explanations should be as simple as possible. However, there are several different statistical strategies that can be used to approximate simple structure and the decision about which strategy to use is again a subjective one.

The major distinction between strategies to achieve simple structure is oblique versus orthogonal rotation of factors. As the labels imply, oblique rotation allows the factors to be correlated with each other whereas orthogonal rotation constrains the factors to be uncorrelated. Most factor analyses use an orthogonal rotation based on a specific strategy called 'Varimax'. Although other orthogonal strategies exist (e.g., Equimax, Quartimax) the differences among these in terms of rotational results are usually slight and one seldom encounters these alternative orthogonal approaches. Orthogonal approaches to the rotation of personality factors probably dominate in the literature because of their computational simplicity relative to oblique rotations. However, the issue of computational simplicity is no longer of much concern with the computer power available today so the continued preference for orthogonal rotations may, as with the preference for PC over PF, be historically rather than scientifically based.

Oblique rotations of personality factors have some distinct advantages over orthogonal rotations. In general these advantages result because oblique rotations are less constrained than orthogonal ones. That is, oblique rotations *allow* the factors to be correlated with each other, whereas orthogonal rotations *force* the factors to be uncorrelated. Thus, in the pursuit of simple structure, oblique rotations will be more successful than orthogonal ones because oblique rotations have more flexibility. Oblique rotations can, in some sense, transfer the complexity of items that are not simple (load on more than one factor) to the factors by making the relations among the factors more complex. Perhaps the best way to appreciate the advantage of oblique rotations over orthogonal ones is to note that if the simple structure factors are orthogonal or nearly so, oblique rotations will leave the factors essentially uncorrelated and oblique rotations will become identical (or nearly so) to orthogonal ones. A second advantage of oblique rotations of personality factors is that it allows the investigator

to explore higher order factor models—that is factors of factors. Two of the systems shown in Table 1, Digman's Alpha and Beta factors and Cattell's five Global Factors for the 16 PF represent such higher order factor solutions.

Simple structure is generally accepted as a goal of factor rotation and is the basis for all the specific rotational strategies available in standard factor analytic software. However, within the field of personality there has been some theoretical recognition that simple structure may not be the most appropriate way to conceptualize personality. The best historical example of this view is the interpersonal circle of Leary, Wiggins, and others [14]. A circular arrangement of items around two orthogonal axes means that some items must load equally highly on both factors, which is not simple structure. In the interpersonal circle, for example, an item such as 'trusting' has both loving and submissive aspects, and so would load complexly on both the Love-Hate and Dominance-Submission factors. Likewise, 'cruel' has both Dominant and hateful aspects. More recently, a complex version of the Big Five called the *AB5C structure* that explicitly recognizes that many personality items are blends of more than one factor was introduced by [8]. In using factor analysis to identify or evaluate circumplex models or any personality models that explicitly view personality items as blends of factors, simple structure will not be an appropriate criterion for arranging the factors.

What Should the Factors be Called? In previous sections the importance of the meaningfulness and interpretation of personality factors as a basis for evaluating the acceptability of a factor solution has been emphasized. But, of course, the interpretation and naming of factors is another source of the inherent subjectivity in the process. This subjectivity is no different than the subjectivity of all of science when it comes to interpreting the results – but the fact that different, but reasonable, scientists will often disagree about the meaning or implications of the same data certainly applies to the results of a factor analysis.

The interpretation problem in factor analysis is perhaps particularly pronounced because factors, personality or otherwise, have no objective reality. Indeed, factors do not result from a factor analysis, rather the result is a matrix of factor loadings such as

the one shown in Figure 1. On the basis of the content of the items and their loadings in the matrix, the 'nature' of the factor is inferred. That is, we know a factor through the variables with which it is correlated. It is because factors do not exist and are not, therefore, directly observed that we often call them 'latent' factors. Latent factors have the same properties as other latent variables such as 'depression,' 'intelligence', or 'time'. None of these variables is observed or measured directly, but rather they are measured via observations that are correlated with them such as loss of appetite, vocabulary knowledge, or the movement of the hand on a watch. A second complication is that in the factor analyses described here there are no statistical tests of whether a particular loading is significant; instead different crude standards such as loadings over 0.50 or over 0.30 have been used to decide if an item is 'on' a factor. Different investigators can, of course, decide on different standards, with the result that factors are identified by different items, even in the same analysis.

Thus, it should come as no surprise that different investigators will call the 'same' factor by a different name. Within the domain of the interpersonal circle, for example, the factors have been called *Love and Hate*, or *Affiliation and Dominance*. Within the Big Five, various labels have been applied to each factor, as shown in Table 2. Although there is a degree of similarity among the labels in each column, there are clear interpretive differences as well. The implication of this point is that one should not simply look at the name or interpretation an investigator applies to a factor, but also at the factor-loading matrix so that the basis for the interpretation can be evaluated. It is not uncommon to see the same label applied to somewhat different patterns of loadings, or for different labels to be applied to the same pattern of loadings.

Some investigators, perhaps out of recognition of the difficulty and subjectivity of factor naming, have eschewed applying labels at all and instead refer to factors by number. Thus, in the literature on the Big Five, one may see reference to Factors I, II, III, IV, V. Of course, those investigators know the 'names' that are typically applied to the numbered factors and these are shown in Table 2. Another approach has been to name the factors with uncommon labels to try to separate the abstract scientific meaning of a factor from its everyday interpretation. In particular, Cattell used this approach with the 16PF, where he applied labels to his factors such as 'Parmia', 'Premsia', 'Autia', and so on. Of course, translations of these labels into their everyday equivalents soon appeared (Parmia is 'Social Boldness', Premsia is 'Sensitivity', and Autia is 'Abstractedness'), but the point can be appreciated, even if not generally followed.

A Note on Confirmatory Factor Analysis. This presentation of factor analysis of personality measures has focused almost exclusively on approaches to factor analysis that are often referred to as 'exploratory' (see **Factor Analysis: Exploratory**). This label is somewhat misleading as it implies that investigators use factor analysis just to 'see what happens'. Most investigators are not quite so clueless and the factor analysis of personality items usually takes place under circumstances where the investigator has some specific ideas about what items should be included in the set to be factored, and hypotheses about how many factors there are, what items will be located on the same factor, and even what the factors will be called. In this sense, the analysis has some 'confirmatory' components.

In fact the term 'exploratory' refers to the fact that in these analyses a correlation matrix is submitted for analyses and the analyses generates the optimal

Table 2 Some of the different names applied to the Big Five personality factors in different systems

Factor I	Factor II	Factor III	Factor IV	Factor V
Extroversion	Agreeableness	Conscientiousness	Emotional Stability	Openness to Experience
Surgency	Femininity	High Ego Control	Neuroticism (r)	Intellect
Power	Love	Prudence	Adjustment	Imagination
Low Ego Control	Likeability	Work Orientation	Anxiety (r)	Rebelliousness
Sociability		Impulsivity (r)		

Note: r = label is reversed relative to the other labels.

factors and loadings empirically for that sample of data and without regard to the investigators ideas and expectations. Thus the investigator's beliefs do not guide the analyses and so they are not directly tested. Indeed, there is no hypothesis testing framework within exploratory factor analysis and this is why most decisions associated with this approach to factor analysis are subjective.

The term confirmatory factor analysis (CFA) (*see* **Factor Analysis: Confirmatory**) is generally reserved for a particular approach that is based on **structural equation modeling** as represented in programs such as LISREL, EQS, or AMOS (*see* **Structural Equation Modeling: Software**). CFA is explicitly guided by the investigators beliefs and hypotheses. Specifically, the investigator indicates the number of factors, designates the variables that load on each factor, and indicates if the factors are correlated (oblique) or uncorrelated (orthogonal). The analyses then proceed to generate a hypothetical correlation matrix based on the investigator's specifications and this matrix is compared to the empirical correlation matrix based on the items. Chi-square goodness-of-fit tests and various modifications of these as 'fit indices' are available for evaluating how close the hypothesized matrix is to the observed matrix. In addition, the individual components of the model such as the loadings of individual variables on specific factors and proposed correlations among the factors can be statistically tested. Finally, the increment in the goodness-of-fit of more complex models relative to simpler ones can be tested to see if the greater complexity is warranted.

Clearly, when investigators have some idea about what type of factor structure should emerge from their analysis, and investigators nearly always have such an idea, CFA would seem to be the method of choice. However, the application of CFA to personality data has been slow to develop and is not widely used. The primary reason for this is that CFA does not often work well with personality data. Specifically, even when item sets that seem to have a well-established structure such as those contained in the Big Five Inventory (BFI-44 [2]) or the Eysenck Personality Questionnaire (EPQ [5]) are subjected to CFA based on that structure, the fit of the established structure to the observed correlations is generally below the minimum standards of acceptable fit.

The obvious interpretation of this finding is that factor analyses of personality measures do not lead

to structures that adequately summarize the complex relations among those measures. This interpretation is undoubtedly correct. What is not correct is the further conclusion that structures such as those represented by five or three or seven factors, or circumplexes, or whatever are therefore useless or misleading characterizations of personality.

Factor analyses of personality measures are intended to simplify the complex observed relations among personality measures. Thus, it is not surprising that factor analytic solutions do not summarize all the variation and covariation among personality measures. The results of CFA are indicating that factor analytic models of personality simply do not capture all the complexity in human personality, but this is not their purpose. To adequately represent this complexity items would need to load on a number of factors (no simple structure); factors would need to correlate with each other (oblique rotations), and many small factors representing only one or two items might be required. Moreover, such structures might well be specific to a given sample and would not generalize. The cost of 'correctly' modeling personality would be the loss of the simplicity that the factor analysis was initially designed to provide. Certainly the factor analysis of personality measures is an undertaking where Whitehead's dictum, 'Seek simplicity but distrust it', applies.

CFA can still be a powerful tool for evaluating the relations among personality measures. The point of this discussion is simply that CFA should not be used to decide if a particular factor analytic model is 'correct'; as the model almost certainly is not correct because it is too simple. Rather, CFA should be used to compare models of personality by asking if adding more factors or correlations among factors significantly improves the fit of a model. That is, when the question is changed from, 'Is the model correct'?, to 'Which model is significantly better'? CFA can be a most appropriate tool. Finally, it is important to note that CFA also does not address the decision in factor analysis of personality measures that probably has the most crucial impact on the results. This is the initial decision about what variables are to be included in the analysis.

Summary

Factor analysis of personality measures has resulted in a wide variety of possible structures of human

personality. This variety results because personality psychologists have different theories about what constitutes the domain of personality and they have different views about the goals of factor analysis. In addition, different reasonable criteria exist for determining the number of factors and for rotating and naming those factors. Thus, the evaluation of any factor analysis must include not simply the end result, but all the decisions that were made on the way to achieving that result. The existence of many reasonable factor models of human personality suggests that people are diverse not only in their personality, but in how they perceive personality.

Factor Score Estimation

Introduction

Factor analysis is concerned with two problems. The first problem is concerned with determining a factor pattern matrix based on either the **principal components analysis** or the common factor model. Factor loadings in the pattern matrix indicate how highly the observed variables are related to the principal components or the common factors, both of which can be thought of as **latent variables**. The second problem is concerned with estimating latent variable scores for each case. Latent variable scores, commonly referred to as *factor scores*, are useful and often necessary. Consider that the number of observed variables may be large; obtaining the (typically fewer) factor scores facilitates subsequent analyses. To cite another example, factor scores – at least when derived under the common factor model – are likely to be more reliable than observed scores. Related to the idea of higher reliability is the belief that a factor score is a pure, *univocal* (homogenous) measure of a latent variable, while an observed score may be ambiguous because we do not know what combination of latent variables may be represented by that observed score.

A number of methods have been proposed for obtaining factor scores. When these methods are applied to factors derived under the principal components model, the scores are ‘exact’, exact in the sense that a unique set of factor scores can be found for the principal components that are supposed to denote their true population values. It does not matter whether scores are derived for all n components, or only for some m ($m \leq n$) of them. In contrast, factor scores are not uniquely determinable for the factors of the common factor model: An infinite number of sets of factor scores are possible for any one set of common factors and thus, their true values must be estimated. Factor score indeterminacy arises from the indeterminacy of the common factor model itself.

Principal Component Scores

Factor scores computed for a set of principal components – henceforth to be referred to as *principal component scores* – are straightforwardly calculated.

As noted above, this is true no matter how many of the n possible principal components are retained.

In order to describe principal component scores, we begin with a matrix equation for a single case in which only m of the principal components have been retained:

$$\mathbf{Z}_{n \times 1} = \mathbf{A}_{n \times m} \mathbf{F}_{m \times 1}, \quad (1)$$

where $\mathbf{Z}$ is an $n \times 1$ column vector of n standardized observed variables, $\mathbf{A}$ is an $n \times m$ pattern matrix of the loadings of n observed variables on the m principal components, and $\mathbf{F}$ is an $m \times 1$ column vector of m principal component scores. The principal component scores are given by

$$\begin{aligned} \mathbf{F}_{m \times 1} &= \mathbf{A}_{n \times m}^{-1} \mathbf{Z}_{n \times 1} \\ \mathbf{A}' \mathbf{Z} &= \mathbf{A}' \mathbf{A} \mathbf{F} \\ &= (\mathbf{A}' \mathbf{A})^{-1} \mathbf{A}' \mathbf{Z} \\ &= \Lambda'_{D_{n \times n}} \mathbf{A}_{m \times n}^{-1} \mathbf{Z}_{n \times 1}, \end{aligned} \quad (2)$$

where λ_D is an $m \times m$ diagonal matrix of m eigenvalues. Equation (2) implies that a principal component score is constructed in the following way. First, each of the n loadings (symbolized by a) from the principal component's column in pattern matrix $\mathbf{A}$ is divided by the eigenvalue (λ) of the principal component (i.e., a/λ). Second, a/λ is multiplied by the score of the observed variable z associated with the loading (i.e., $a/\lambda \times z$). And then third, the n $a/\lambda \times z$ terms are summed, constructing the principal component f from their linear combination:

$$f_k = \sum_{j=1}^n \frac{a_{jk}}{\lambda_k} \times z_j, \quad (3)$$

where a_{jk} is the loading for the j th observed variable ($j = 1, 2, \dots, n$) on the k th principal component ($k = 1, 2, \dots, m, m \leq n$), and λ_k is the eigenvalue of the k th principal component.

For example, assume we have retained three principal components from eight observed variables:

$$\mathbf{A} = \begin{bmatrix} .71 & .11 & .16 \\ .82 & .15 & .20 \\ .93 & .19 & .24 \\ .10 & .77 & .28 \\ .22 & .88 & .32 \\ .24 & .21 & .36 \\ .28 & .23 & .71 \\ .39 & .32 & .77 \end{bmatrix} \quad (4)$$

2 Factor Score Estimation

and the eight observed scores for a person are

$$\mathbf{z} = \begin{bmatrix} .10 \\ .22 \\ -.19 \\ -.25 \\ .09 \\ .23 \\ .15 \\ -.19 \end{bmatrix}. \quad (5)$$

The three eigenvalues are, respectively, 2.39, 1.64, and 1.53. The first, second, and third principle component scores are calculated as

$$\begin{aligned} f_1 &= .04 = \left(\frac{.71}{2.39} \times .10 \right) + \left(\frac{.82}{2.39} \times .22 \right) \\ &\quad + \left(\frac{.93}{2.39} \times -.19 \right) + \left(\frac{.10}{2.39} \times -.25 \right) \\ &\quad + \left(\frac{.22}{2.39} \times .09 \right) + \left(\frac{.24}{2.39} \times .23 \right) \\ &\quad + \left(\frac{.28}{2.39} \times .15 \right) + \left(\frac{.39}{2.39} \times -.19 \right) \\ f_2 &= -.05 = \left(\frac{.11}{1.64} \times .10 \right) + \left(\frac{.15}{1.64} \times .22 \right) \\ &\quad + \left(\frac{.19}{1.64} \times -.19 \right) + \left(\frac{.77}{1.64} \times -.25 \right) \\ &\quad + \left(\frac{.88}{1.64} \times .09 \right) + \left(\frac{.21}{1.64} \times .23 \right) \\ &\quad + \left(\frac{.23}{1.64} \times .15 \right) + \left(\frac{.32}{1.64} \times -.19 \right) \\ f_3 &= .01 = \left(\frac{.16}{1.53} \times .10 \right) + \left(\frac{.20}{1.53} \times .22 \right) \\ &\quad + \left(\frac{.24}{1.53} \times -.19 \right) + \left(\frac{.28}{1.53} \times -.25 \right) \\ &\quad + \left(\frac{.32}{1.53} \times .09 \right) + \left(\frac{.36}{1.53} \times .23 \right) \\ &\quad + \left(\frac{.71}{1.53} \times .15 \right) + \left(\frac{.77}{1.53} \times -.19 \right). \end{aligned} \quad (6)$$

Component scores can be computed using either the unrotated pattern matrix or the rotated pattern matrix; both are of equivalent statistical validity. The scores obtained using the rotated matrix are simply

rescaled transformations of scores obtained using the unrotated matrix.

Common Factor Scores

Why are Common Factor Scores Indeterminate?

Scores from the common factor model are estimated because it is mathematically impossible to determine a unique set of them – an infinite number of such sets exist. This results from the *underidentification* of the common factor model (*see Factor Analysis: Exploratory; Identification*). An underidentified model is a model for which not enough information in the data is present to estimate all of the model's unknown parameters. In the principal components model, identification is achieved by imposing two restrictions: (a) the first component accounts for the maximum amount of variance possible, the second the next, and so on and so forth, and (b) the components are uncorrelated with each other. Imposing these two restrictions, the unknown parameters in the principal components model – the $n \times m$ factor loadings – can be uniquely estimated. Thus, the principal components model is identified: The $n \times m$ factor loadings to be estimated are $\leq$ in number to the $n(n+1)/2$ correlations available to estimate them.

In contrast, even with the imposition of the two restrictions, the common factor model remains underidentified for the following reason. The model postulates not only the existence of m common factors underlying n variables, requiring the specification of $n \times m$ factor loadings (as in the principal components model), it also postulates the existence of n specific factors, resulting in a model with $(n \times m) + n$ parameters to be estimated, greater in number than the $n(n+1)/2$ available to estimate them. As a result, the $n \times m$ factor loadings have an infinite number of possible values. Logically then, the factor scores would be expected to have an infinite number of possible values.

Methods for Estimating Common Factor Scores

Estimation by Regression

Thomson [9] was the first to suggest that ordinary least-squares regression methods (*see Least Squares Estimation*) can be used to obtain estimates of factor

scores. The information required to find the regression weights for the factors on the observed variables – the correlations among the observed variables and the correlation between the factors and observed variables – is available from the factor analysis. The least-squares criterion is to minimize the sum of the squared differences between predicted and true factor scores, which is analogous to the generic least-squares criterion of minimizing the sum of the squared differences between predicted and observed scores.

We express the linear regression of any factor f on the observed variables z in matrix form for one case as

$$\hat{\mathbf{F}}_{1 \times m} = \mathbf{Z}_{1 \times n} \mathbf{B}_{n \times m}, \quad (7)$$

where $\mathbf{B}$ is a matrix of weights for the regression of the m factors on the n observed variables, and $\hat{\mathbf{F}}$ is a row vector of m estimated factor scores.

When the common factors are orthogonal, we use the following matrix equation to obtain $\mathbf{B}$:

$$\mathbf{B}_{n \times m} = \mathbf{R}_{n \times n}^{-1} \mathbf{A}_{n \times m}, \quad (8)$$

where $\mathbf{R}$ is the matrix of correlations between the n observed variables. If the common factors are nonorthogonal, we also require Φ , the correlation matrix among the m factors:

$$\mathbf{B}_{n \times m} = \mathbf{R}_{n \times n}^{-1} \mathbf{A}_{n \times m} \Phi_{m \times m}. \quad (9)$$

To illustrate the regression method, we perform a common factor analysis on a set of six observed variables, retaining nonorthogonal two factors. We use data from three cases and define

$$\mathbf{Z} = \begin{bmatrix} 0.00 & -0.57 & -1.15 & 0.00 & -1.12 & -0.87 \\ -1.00 & -0.57 & 0.57 & 0.00 & 0.80 & -0.21 \\ 1.00 & 1.15 & 0.57 & 0.00 & 0.32 & 1.09 \end{bmatrix},$$

$$\mathbf{R} = \begin{bmatrix} 1.00 & & & & & \\ 0.31 & 1.00 & & & & \\ 0.48 & 0.54 & 1.00 & & & \\ 0.69 & 0.31 & 0.45 & 1.00 & & \\ 0.34 & 0.30 & 0.26 & 0.41 & 1.00 & \\ 0.37 & 0.41 & 0.57 & 0.39 & 0.38 & 1.00 \end{bmatrix},$$

$$\mathbf{A} = \begin{bmatrix} 0.65 & 0.19 \\ 0.59 & 0.08 \\ 0.59 & 0.17 \\ 0.12 & 0.72 \\ 0.14 & 0.70 \\ 0.24 & 0.34 \end{bmatrix},$$

$$\Phi = \begin{bmatrix} 1.00 & \\ 0.45 & 1.00 \end{bmatrix}. \quad (10)$$

On the basis of (9), the regression weights are

$$\begin{aligned} \mathbf{B} &= \begin{bmatrix} 1.00 & & & & & \\ 0.31 & 1.00 & & & & \\ 0.48 & 0.54 & 1.00 & & & \\ 0.69 & 0.31 & 0.45 & 1.00 & & \\ 0.34 & 0.30 & 0.26 & 0.41 & 1.00 & \\ 0.37 & 0.41 & 0.57 & 0.39 & 0.38 & 1.00 \end{bmatrix}^{-1} \\ &\quad \times \begin{bmatrix} 0.65 & 0.19 \\ 0.59 & 0.08 \\ 0.59 & 0.17 \\ 0.12 & 0.72 \\ 0.14 & 0.70 \\ 0.24 & 0.34 \end{bmatrix} \begin{bmatrix} 1.00 & \\ 0.45 & 1.00 \end{bmatrix} \\ &= \begin{bmatrix} 2.05 & & & & & \\ -0.01 & 0.48 & & & & \\ -0.41 & -0.64 & 1.99 & & & \\ -1.18 & -0.01 & -0.20 & 2.11 & & \\ -0.09 & -0.20 & 0.16 & -0.35 & 1.32 & \\ -0.02 & -0.14 & -0.70 & -0.12 & -0.33 & 1.64 \end{bmatrix} \\ &\quad \times \begin{bmatrix} 0.65 & 0.19 \\ 0.59 & 0.08 \\ 0.59 & 0.17 \\ 0.12 & 0.72 \\ 0.14 & 0.70 \\ 0.24 & 0.34 \end{bmatrix} \begin{bmatrix} 1.00 & \\ 0.45 & 1.00 \end{bmatrix} \\ &= \begin{bmatrix} 0.65 & -0.19 \\ 0.33 & -0.01 \\ 0.33 & 0.10 \\ -0.29 & 0.42 \\ 0.22 & 0.54 \\ -0.14 & 0.01 \end{bmatrix} \quad (11) \end{aligned}$$

Then, based on (7), the two-factor scores for the three cases are

$$\begin{aligned} \hat{\mathbf{F}} &= \begin{bmatrix} 0.00 & -0.57 & -1.15 & 0.00 & -1.12 & -0.87 \\ -1.00 & -0.57 & 0.57 & 0.00 & 0.80 & -0.21 \\ 1.00 & 1.15 & 0.57 & 0.00 & 0.32 & 1.09 \end{bmatrix} \\ &\quad \times \begin{bmatrix} 0.65 & -0.19 \\ 0.33 & -0.01 \\ 0.33 & 0.10 \\ -0.29 & 0.42 \\ 0.22 & 0.54 \\ -0.14 & 0.01 \end{bmatrix} \end{aligned}$$

4 Factor Score Estimation

$$= \begin{bmatrix} -0.69 & -0.72 \\ -0.44 & 0.68 \\ 1.14 & 0.04 \end{bmatrix} \quad (12)$$

The regression estimates have the following properties:

1. The multiple correlation between each factor score and the common factors is maximized.
2. Each factor score estimate $\hat{f}$ is uncorrelated with its own residual $f - \hat{f}$ and the residual of every other estimate.
3. Even when the common factors are orthogonal, the estimates $\hat{f}$ are mutually correlated.
4. Even when the common factors are orthogonal, the estimate $\hat{f}$ of one factor can be correlated with any of the other $m - 1$ common factors.
5. Factor scores obtained through regression are biased estimates of their population values.

Depending on one's point of view as to what properties factor scores should have, properties 3 and 4 may or may not be problematic. If one believes that the univocality of a factor is diminished when it is correlated with another factor, then estimating factor scores by regression is considered a significantly flawed procedure. According to this view, univocality is compromised when variance in the factor is in part due to the influence of other factors. According to an alternative view, if in the population factors are correlated, then their estimated scores should be as well.

Minimizing Unique Factors

Bartlett [2] proposed a method of factor score estimation in which the least-squares criterion is to minimize the difference between the predicted and unique factor scores instead of minimizing the difference between the predicted and 'true' factor scores that is used in regression estimation. Unlike the regression method, Bartlett's method produces a factor score estimate that only correlates with its own factor and not with any other factor. However, correlations among the estimated scores of different factors still remain. In addition, Bartlett estimates, again unlike regression estimates, are unbiased. This is because they are **maximum likelihood estimates** of the population factor scores: It is assumed that the unique factor scores are multivariate normally

distributed (*see Catalogue of Probability Density Functions*).

Bartlett's method specifies that for one case

$$\mathbf{Z}_{1 \times n} = \hat{\mathbf{F}}_{1 \times m} \mathbf{A}_{m \times n} + \hat{\mathbf{V}}_{1 \times n} \mathbf{U}_{n \times n}, \quad (13)$$

where $\mathbf{Z}$ is a row vector of n observed variables scores, $\hat{\mathbf{F}}$ is a column vector of m estimated factor scores, $\mathbf{A}$ is the factor pattern matrix of loadings for the n observed variables on the m factors, $\hat{\mathbf{V}}$ is a row vector of n estimated unique scores, and $\mathbf{U}$ is a diagonal matrix of the standard deviations of the n unique factors. The common factor analysis provides both $\mathbf{A}$ and $\mathbf{U}$.

Recalling that $\hat{\mathbf{F}}_{1 \times m} = \mathbf{Z}_{1 \times n} \mathbf{B}_{n \times m}$ (1), we obtain the factor score weight matrix $\mathbf{B}$ to estimate the factor scores in $\hat{\mathbf{F}}$:

$$\begin{aligned} \mathbf{B}_{n \times m} &= \mathbf{U}_{n \times n}^{-2} \mathbf{A}_{n \times m} (\mathbf{A}'_{m \times n} \mathbf{U}_{n \times n}^{-2} \mathbf{A}_{n \times m})^{-1} \cdot \\ \hat{\mathbf{F}}_{1 \times m} &= \mathbf{Z}_{1 \times n} \mathbf{B}_{n \times m} \\ &= \mathbf{Z}_{1 \times n} \mathbf{U}_{n \times n}^{-2} \mathbf{A}_{n \times m} (\mathbf{A}'_{m \times n} \mathbf{U}_{n \times n}^{-2} \mathbf{A}_{n \times m})^{-1}. \end{aligned} \quad (14)$$

$\mathbf{U}^{-2}$ is the inverse of a diagonal matrix of the variances of the n unique factor scores. Using the results from (14), we can obtain the unique factor scores with

$$\hat{\mathbf{V}}_{1 \times n} = \mathbf{Z}_{1 \times n} \mathbf{U}_{n \times n}^{-1} - \hat{\mathbf{F}}_{1 \times m} \mathbf{A}_{m \times n} \mathbf{U}_{n \times n}^{-1}. \quad (15)$$

For our example of Bartlett's method, we define $\mathbf{U}^2$ as a diagonal matrix of the n unique factor variances,

$$\mathbf{U}^2 = \begin{bmatrix} 0.41 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.61 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.43 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.39 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.75 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.54 \end{bmatrix}, \quad (16)$$

and $\mathbf{U}$ as a diagonal matrix of the n unique factor standard deviations,

$$\mathbf{U} = \begin{bmatrix} 0.64 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.78 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.66 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.62 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.87 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.73 \end{bmatrix}. \quad (17)$$

Following (14), the factor score weight matrix is obtained by

$$\begin{aligned}
 \mathbf{B} &= \begin{bmatrix} 0.41 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.61 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.43 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.39 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.75 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.54 \end{bmatrix}^{-2} \\
 &\times \begin{bmatrix} 0.65 & 0.19 \\ 0.59 & 0.08 \\ 0.59 & 0.17 \\ 0.12 & 0.72 \\ 0.14 & 0.70 \\ 0.24 & 0.34 \end{bmatrix} \left(\begin{bmatrix} 0.65 & 0.19 \\ 0.59 & 0.08 \\ 0.59 & 0.17 \\ 0.12 & 0.72 \\ 0.14 & 0.70 \\ 0.24 & 0.34 \end{bmatrix} \right)' \\
 &\times \begin{bmatrix} 0.41 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.61 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.43 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.39 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.75 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.54 \end{bmatrix}^{-2} \\
 &\times \begin{bmatrix} 0.65 & 0.19 \\ 0.59 & 0.08 \\ 0.59 & 0.17 \\ 0.12 & 0.72 \\ 0.14 & 0.70 \\ 0.24 & 0.34 \end{bmatrix}^{-1} \\
 &= \begin{bmatrix} 2.44 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 1.64 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 2.38 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 2.63 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 1.33 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 1.85 \end{bmatrix} \\
 &\times \begin{bmatrix} 0.65 & 0.19 \\ 0.59 & 0.08 \\ 0.59 & 0.17 \\ 0.12 & 0.72 \\ 0.14 & 0.70 \\ 0.24 & 0.34 \end{bmatrix}^{-1} \\
 &= \begin{bmatrix} 1.59 & 0.46 \\ 0.97 & 0.13 \\ 1.40 & 0.40 \\ 0.31 & 1.89 \\ 0.19 & 0.93 \\ 0.44 & 0.63 \end{bmatrix} \\
 &\times \begin{bmatrix} 0.48 & -0.23 \\ -0.23 & 0.52 \end{bmatrix} \\
 &= \begin{bmatrix} 0.66 & -0.17 \\ 0.44 & -0.15 \\ 0.59 & -0.11 \\ -0.28 & 0.92 \\ -0.12 & 0.45 \\ 0.07 & 0.23 \end{bmatrix}. \tag{18}
 \end{aligned}$$

With $\mathbf{B}$ defined as above, the estimated common factor scores for the three cases are

$$\begin{aligned}
 \hat{\mathbf{F}} &= \begin{bmatrix} 0.00 & -0.57 & -1.15 & 0.00 & -1.12 & -0.87 \\ -1.00 & -0.57 & 0.57 & 0.00 & 0.80 & -0.21 \\ 1.00 & 1.15 & 0.57 & 0.00 & 0.32 & 1.09 \end{bmatrix} \\
 &\times \begin{bmatrix} 0.66 & -0.17 \\ 0.44 & -0.15 \\ 0.59 & -0.11 \\ -0.28 & 0.92 \\ -0.12 & 0.45 \\ 0.07 & 0.23 \end{bmatrix} \\
 &= \begin{bmatrix} -0.85 & -0.49 \\ -0.69 & 0.45 \\ 1.54 & 0.04 \end{bmatrix}, \tag{19}
 \end{aligned}$$

and from (15), the unique factor scores for the three cases are

6 Factor Score Estimation

&= \begin{bmatrix} 0.00 & -0.73 & -1.74 & 0.00 & -1.29 & -1.19 \\ -1.56 & -0.73 & 0.86 & 0.00 & 0.92 & -0.29 \\ 1.56 & 1.47 & 0.86 & 0.00 & 0.36 & 1.49 \end{bmatrix} - \begin{bmatrix} -0.41 & -0.42 & -0.39 & -0.28 & -0.40 & -0.27 \\ -0.23 & -0.28 & -0.22 & 0.15 & 0.19 & -0.01 \\ 0.64 & 0.71 & 0.60 & 0.13 & 0.21 & 0.28 \end{bmatrix} \\
&= \begin{bmatrix} 0.41 & -0.31 & -1.39 & 0.28 & -0.89 & -0.92 \\ -1.33 & -0.44 & 1.09 & -0.15 & 0.73 & -0.27 \\ 0.92 & 0.76 & 0.28 & -0.13 & 0.16 & 1.21 \end{bmatrix} \tag{20}
\end{aligned}$$

Bartlett factor score estimates can always be distinguished from regression factor score estimates by examining the variance of the factor scores. While regression estimates have variances ≤ 1 , Bartlett estimates have variances ≥ 1 [7]. This can be explained as follows: The regression estimation procedure divides the factor score f into two uncorrelated parts, the regression part $\hat{f}$ and the residual part $f - \hat{f}$.

Thus,

$$f = \hat{f} + e, \tag{21}$$

where

$$e = f - \hat{f}. \tag{22}$$

Since the e are assumed multivariate normally distributed, the $\hat{f}$ can further be written as the sum

of the factor score f and a residual ε :

$$\hat{f} = f + \varepsilon, \tag{23}$$

where

$$\varepsilon = \hat{f} - f. \tag{24}$$

The result is that the variance of $\hat{f}$ is the sum of the unit variance of f and the variance of ε , the error about the true value.

Uncorrelated Scores Minimizing Unique Factors

Anderson and Rubin [1] revised Bartlett's method so that factor score estimates are both uncorrelated the $m - 1$ with the other factors and are not correlated with each other. These two properties result

from the following matrix equation for the factor score estimates:

$$\hat{\mathbf{F}} = \mathbf{Z}_{1 \times n} \mathbf{U}_{n \times n}^{-2} \mathbf{A}_{n \times m} (\mathbf{A}_{m \times n}' \mathbf{U}_{n \times n}^{-2} \Phi_{n \times n} \mathbf{U}_{n \times n} \mathbf{A}_{n \times m})^{-1/2}, \quad (25)$$

where Φ is a matrix of factor correlations.

While resembling (14), (25) is substantially more complex to solve: The term, $\mathbf{A}_{m \times n}' \mathbf{U}_{n \times n}^{-2} \Phi_{n \times n} \mathbf{U}_{n \times n} \mathbf{A}_{n \times m}$, is raised to a power of $-1/2$. This power indicates that the inversion of the symmetric square root of the matrix product is required. The symmetric square root of a matrix can be found for any positive definite symmetric matrix. To illustrate, we define $\mathbf{G}$ as an $n \times n$ positive semidefinite symmetric matrix. The symmetric square root of $\mathbf{G}$, $\mathbf{G}^{1/2}$, must meet the following condition:

$$\mathbf{G}_{n \times n} = \mathbf{G}_{n \times n}^{1/2} \mathbf{G}_{n \times n}^{1/2}. \quad (26)$$

Perhaps the most straightforward method of obtaining $\mathbf{G}^{1/2}$ is to obtain the spectral decomposition of $\mathbf{G}$, such that $\mathbf{G}$ can be reproduced by a function of its eigenvalues (λ) and eigenvectors (x):

$$\mathbf{G}_{n \times n} = \mathbf{X}_{n \times n} \Lambda_{D_{n \times n}} \mathbf{X}_{n \times n}', \quad (27)$$

where $\mathbf{X}$ is an $n \times n$ matrix of eigenvectors and Λ_D is an $n \times n$ diagonal matrix of eigenvalues. It follows then that

$$\mathbf{G}_{n \times n}^{1/2} = \mathbf{X}_{n \times n} \Lambda_{D_{n \times n}}^{1/2} \mathbf{X}_{n \times n}'. \quad (28)$$

If we set $\mathbf{G}^{1/2} = \mathbf{A}_{m \times n}' \mathbf{U}_{n \times n}^{-2} \Phi_{n \times n} \mathbf{U}_{n \times n} \mathbf{A}_{n \times m}$, (25) can now be rewritten as

$$\hat{\mathbf{F}} = \mathbf{Z}_{1 \times n} \mathbf{U}_{n \times n}^{-2} \mathbf{A}_{n \times m} \mathbf{G}^{-1/2}. \quad (29)$$

To illustrate the Anderson and Rubin method, we specify

$$\mathbf{X} = \begin{bmatrix} 0.74 & -0.67 \\ 0.67 & 0.74 \end{bmatrix} \quad (30)$$

and

$$\Lambda = \begin{bmatrix} 23.73 & 0.00 \\ 0.00 & 1.64 \end{bmatrix}. \quad (31)$$

Then, for $\mathbf{A}_{m \times n}' \mathbf{U}_{n \times n}^{-2} \Phi_{n \times n} \mathbf{U}_{n \times n} \mathbf{A}_{n \times m}$, the spectral decomposition is

$$\mathbf{G} = \begin{bmatrix} 0.74 & -0.67 \\ 0.67 & 0.74 \end{bmatrix} \begin{bmatrix} 23.73 & 0.00 \\ 0.00 & 1.64 \end{bmatrix} \times \begin{bmatrix} 0.74 & -0.67 \\ 0.67 & 0.74 \end{bmatrix}' \quad (32)$$

and therefore

$$\begin{aligned} \mathbf{G}^{1/2} &= \begin{bmatrix} 0.74 & -0.67 \\ 0.67 & 0.74 \end{bmatrix} \begin{bmatrix} 23.73 & 0.00 \\ 0.00 & 1.64 \end{bmatrix}^{1/2} \\ &\quad \times \begin{bmatrix} 0.74 & -0.67 \\ 0.67 & 0.74 \end{bmatrix}' \\ &= \begin{bmatrix} 0.74 & -0.67 \\ 0.67 & 0.74 \end{bmatrix} \begin{bmatrix} 4.87 & 0.00 \\ 0.00 & 1.28 \end{bmatrix} \begin{bmatrix} 0.74 & -0.67 \\ 0.67 & 0.74 \end{bmatrix}' \\ &= \begin{bmatrix} 3.26 & 1.79 \\ 1.79 & 2.89 \end{bmatrix}. \end{aligned} \quad (33)$$

Then, from Equation

$$\begin{aligned} \hat{\mathbf{F}} &= \begin{bmatrix} 0.00 & -0.57 & -1.15 & 0.00 & -1.12 & -0.87 \\ -1.00 & -0.57 & 0.57 & 0.00 & 0.80 & -0.21 \\ 1.00 & 1.15 & 0.57 & 0.00 & 0.32 & 1.09 \end{bmatrix} \\ &\quad \times \begin{bmatrix} 0.41 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.61 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.43 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.39 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.75 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.54 \end{bmatrix}^{-2} \\ &\quad \times \begin{bmatrix} 0.65 & 0.19 \\ 0.59 & 0.08 \\ 0.59 & 0.17 \\ 0.12 & 0.72 \\ 0.14 & 0.70 \\ 0.24 & 0.34 \end{bmatrix} \begin{bmatrix} 3.26 & 1.79 \\ 1.79 & 2.89 \end{bmatrix}^{-1} \\ &= \begin{bmatrix} 0.00 & -0.57 & -1.15 & 0.00 & -1.12 & -0.87 \\ -1.00 & -0.57 & 0.57 & 0.00 & 0.80 & -0.21 \\ 1.00 & 1.15 & 0.57 & 0.00 & 0.32 & 1.09 \end{bmatrix} \\ &\quad \times \begin{bmatrix} 2.44 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 1.64 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 2.38 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 2.63 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 1.33 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 1.85 \end{bmatrix} \\ &\quad \times \begin{bmatrix} 0.65 & 0.19 \\ 0.59 & 0.08 \\ 0.59 & 0.17 \\ 0.12 & 0.72 \\ 0.14 & 0.70 \\ 0.24 & 0.34 \end{bmatrix} \begin{bmatrix} 0.46 & -0.29 \\ -0.29 & 0.52 \end{bmatrix} \\ &= \begin{bmatrix} 0.00 & -0.57 & -1.15 & 0.00 & -1.12 & -0.87 \\ -1.00 & -0.57 & 0.57 & 0.00 & 0.80 & -0.21 \\ 1.00 & 1.15 & 0.57 & 0.00 & 0.32 & 1.09 \end{bmatrix} \end{aligned}$$

$$\times \begin{bmatrix} 0.60 & -0.21 \\ 0.41 & -0.21 \\ 0.53 & -0.19 \\ -0.40 & 0.90 \\ -0.18 & 0.43 \\ 0.03 & 0.20 \end{bmatrix} = \begin{bmatrix} -0.67 & -0.32 \\ -0.68 & 0.53 \\ 1.35 & -0.20 \end{bmatrix}. \quad (34)$$

The unique factor scores are computed as in the Bartlett method (15). Substituting the results of the Anderson and Rubin method into (15) yields

$$\hat{\mathbf{V}} = \begin{bmatrix} 0.32 & -0.40 & -1.44 & 0.19 & -1.01 & -0.99 \\ -1.34 & -0.45 & 1.07 & -0.18 & 0.68 & -0.30 \\ 1.03 & 0.86 & 0.36 & -0.01 & 0.33 & 1.31 \end{bmatrix} \quad (35)$$

Conclusion

For convenience, we reproduce the factor scores estimated by the regression, Bartlett, and Anderson and Rubin methods:

Regression	Bartlett
$\begin{bmatrix} -0.69 & -0.72 \\ -0.44 & 0.68 \\ 1.14 & 0.04 \end{bmatrix}$	$\begin{bmatrix} -0.85 & -0.49 \\ -0.69 & 0.45 \\ 1.54 & 0.04 \end{bmatrix}$
Anderson-Rubin	
$\begin{bmatrix} -0.67 & -0.32 \\ -0.68 & 0.53 \\ 1.35 & -0.20 \end{bmatrix}$	

The similarity of the factor score estimates computed by the three methods is striking.

This is in part surprising. Empirical studies have found that although the factor score estimates obtained from different methods correlate substantially, they often have very different values [8]. So

it would seem that the important issue is not which of the three estimation methods should be used, but whether any of them should be used at all due to factor score indeterminacy, implying that only principal component scores should be obtained. Readers seeking additional information on this area of controversy specifically, and factor scores generally, should consult, in addition to those references already cited [3–6, 10].

Factorial Designs

A factorial design is one in which two or more treatments (or classifications for variables such as sex) are investigated simultaneously and, in the ideal case, all possible combinations of each treatment (or classification) occur together in the design. In a one-way design, we might ask whether two different drugs lead to a significant difference in average adjustment scores. In a factorial design, we might ask whether the two drugs differ in effectiveness and whether the effectiveness of the drugs changes when each drug is applied under the administration of four different dosage levels. The first independent variable is the type of drug (with two levels) and the second independent variable is the dosage (with four levels). This design would be a 2×4 factorial ANOVA (see **Analysis of Variance**) design.

A major advantage of a factorial design is that we can evaluate two independent variables in a single experiment, as illustrated in Table 1. Another advantage is that we can evaluate the interaction of the two independent variables.

An Example of a 2×4 ANOVA Design

Table 1 presents hypothetical data in which the mean is presented for adjustment scores under two drugs and four dosage levels. Each of the eight means is based on six observations and the error term is $MS_E = 4.0$. Higher adjustment scores indicate better adjustment. The level of significance is set at an *a priori* level of .01 for each effect in the design. The means in the margins of Table 1 show the overall effects of the two independent variables. Testing the significance of the differences among the overall means can be done with *F* tests, as described by various texts such as [2], [3], or [4].

Taking the two drugs as Factor A, it can be shown that the overall *F* test is $F(1, 40) = 84.92$,

$p < 0.0001$, which is significant at the .01 level. Thus, the adjustment mean of 6.375 for Drug 1 is significantly greater than the adjustment mean of 2.5 for Drug 2. The subjects in this experiment are better adjusted when treated with Drug 1 than Drug 2. Taking the four dosages as Factor B, it can be shown that the overall *F* test is $F(3, 40) = 23.67$, $p < 0.0001$, which is also significant at the 0.01 level. One relatively simple method of evaluating the four overall means of Factor B would be with orthogonal contrasts such as orthogonal polynomials (see **Multiple Comparison Procedures**). Orthogonal contrasts are described by [2], [3], or [4], and can be used in testing main effects in a factorial design just as in a one-way ANOVA. For the four overall means of Factor B, only the linear trend is significant. There is a significant tendency for adjustment to increase linearly with increases in dosage.

The test of the interaction between A and B in Table 1 can be shown ([2], [3], or [4]) to be $F(3, 40) = 6.92$, $p = 0.0007$, which is also significant at a 0.01 level.

Following a significant interaction, many researchers prefer to test simple main effects. That is, they would test the four means separately for Drug 1 and Drug 2. Applying orthogonal polynomials to the four means under Drug 1 would show a significant linear trend with $F(1, 40) = 84.17$, $p < 0.0001$, but no other significant effect. Applying orthogonal polynomials to the four means under Drug 2 would show a linear trend also significant at the .01 level with $F(1, 40) = 7.5$, $p = 0.0092$. With significant linear increases in adjustment for both drugs, such testing of simple main effects does not explain the significant interaction.

It is usually better to evaluate significant interactions with interaction contrasts as described by Boik [1]. In Table 1, it can be shown that the contrast identified by the linear trend for the four dosages is significantly greater under Drug 1 than under Drug 2. That is, the tendency for adjustment to increase linearly from 10 mg to 40 mg is significantly greater under Drug 1 than under Drug 2.

The present example illustrates the problem of testing simple main effects to explain significant interactions. The opposite problem of possible misleading interpretations of overall main effects in the presence of significant interactions is illustrated in Kirk [2, p. 370].

Table 1 Hypothetical data of means for a 2×4 design

	10 mg	20 mg	30 mg	40 mg	Overall
Drug 1	3.0	6.5	7.0	9.0	6.375
Drug 2	1.0	2.0	3.0	4.0	2.5
Overall	2.0	4.25	5.0	6.5	4.4375

Family History Versus Family Study Methods in Genetics

In family research, a sample of index cases, or probands, with the disorder of interest is ascertained and the pattern of morbidity is then investigated in first degree relatives (parents, offspring, siblings) second degree relatives (e.g., uncle, aunts, grandparents), third degree relatives (e.g., cousins) and perhaps more distant family members. Familial aggregation is indicated by a significantly higher rate of the disorder in relatives of the probands than in relatives of a selected control population, or than in the general population [2]. It is important to note that a key issue in this kind of research is making sure individuals are correctly categorized with regard to their affected status. Therefore, the sensitivity (proportion of affected relatives correctly identified as affected) and specificity (proportion of unaffected relatives correctly identified as unaffected) of the methods are important considerations.

The two methods for this kind of research are the family history method and the family study method. In the family history method, one or more family members, usually including the proband, are used as informants to provide information on the pedigree structure and which members are affected. This method offers good specificity, and requires relatively few resources. It provides information on all family members, even those who refuse to participate, are unavailable or are deceased, thus reducing sample bias. Further, it may be more accurate for certain types of socially deviant information that people might be unwilling to admit to in interview for example, substance abuse.

The primary concern in using the family history method relates to poor sensitivity. That is, there may be substantial underreporting of morbidity in family members. This may be due to some disorders being masked or unrecognized, such that the informant is unaware of illness in affected family members. Also, family members may vary in the quality of information they provide, for example, mothers of probands have been shown to be may be better informants than fathers [4]. There is also evidence that using more than one informant improves sensitivity.

Another important drawback is that, even if a relative is identified as having a disorder, it may not be possible to make a definite diagnosis on the basis of hearsay. Access to medical case notes (charts) may help overcome this.

In the family study method, affected status is determined by direct interview and examination of all available consenting relatives. Again, this can be supplemented by examining medical case notes. The major positive advantage of this kind of study is its generally superior sensitivity [1], although the specificity is much the same. It is however, more expensive and time consuming, and less convenient. Additionally, sample ascertainment will be incomplete due to absent, deceased, or refusing family members, thus introducing possible sampling bias because only the most cooperative family members are seen. The family study method may also have inferior sensitivity for 'socially undesirable' traits including substance abuse, antisocial behaviour, or some psychiatric disorders, as individuals may be unwilling to admit present or past symptoms in a direct interview.

Whether to use family history or family study method is an important decision in family research, due to the implications in terms of resources required and extent and accuracy of information obtained. The family history method may be best suited to exploratory studies and identifying interesting pedigrees, while the family study method would be better for studying interesting pedigrees in depth. In practice, family studies often include an element of the family history too in order to complete the information gaps and avoid a selection bias [3].

A final caution is that although both of these methods provide information on the familial clustering of a disorder, they cannot distinguish between genetic and shared environmental effects. These issues can only be addressed by performing twin and/or adoption studies [2].

Family Study and Relative Risk

Our goal in the family study is to investigate the extent to which disorders aggregate in families. We can take as the starting point ascertainment of a series of index cases or probands. Preferably, this should be done in a systematic way, for example, on the basis of a consecutive series of patients referred to a particular clinical service or by linking a register of hospital admissions to a population register. Alternatively, ascertainment strategies may be aimed at detecting all the cases of a particular disorder in a defined population. This can have an advantage over clinical ascertainment, which may be biased in favor of probands with more severe forms of disorder and high levels of comorbidity (multiple coexisting disorders). However, other biases may operate in population-based studies. In particular, there are may be volunteer effects. Individuals who agreed to participate in studies tend to be better educated than nonvolunteers and are less likely to come from socially disadvantaged backgrounds. Furthermore, probands having severe disorders may actually be underrepresented because more severely ill individuals refuse to participate.

Relative risk is often used as a measure of the extent to which common disorders, which do not show obvious Mendelian patterns of inheritance, are familial. In general, the relative risk of a disorder, disease, death, or other outcome is the proportion of individuals exposed to the risk factor who are affected divided by the proportion of affecteds among those not exposed. More specifically, therefore, the relative risk for developing a disorder for individuals related to a proband with that disorder is given by:

Relative risk

$$\begin{aligned}
 & \frac{N \text{ of affected relatives of probands} \div}{N \text{ of all relatives of probands}} \\
 &= \frac{N \text{ of affected relatives of controls} \div}{N \text{ of all relatives of controls}} \\
 &= \frac{\text{Proportion of probands' relatives affected}}{\text{Proportion of controls' relatives affected}} \quad (1)
 \end{aligned}$$

Here, the controls will typically be individuals screened for absence of the disease being studied. However, an alternative which may in practice be

less troublesome to obtain, is a sample of unrelated subjects drawn from the general population who are not screened for the disorder, so that relative risk is estimated as:

$$\frac{\text{Proportion of probands' relatives affected}}{\text{Proportion of population sample affected}} \quad (2)$$

This will tend to give a lower estimate of relative risk because the relatives of healthy controls will tend to have a lower proportion of affecteds than that found in the population as a whole. The size of the relative risk in familial disorders tends to increase according to the degree of relatedness to the proband, such that first-degree relatives (e.g., offspring, siblings) who have half their genes shared with the proband tend to have a higher relative risk than second-degree relatives (e.g., nieces/nephews/grandchildren) who share a quarter of their genes, who in turn have a higher risk than third-degree relatives (e.g., cousins). The extent to which relative risk reduces as a function of decreasing genetic relatedness has been proposed as an indicator of whether multiple genes contributing to a disease interact as opposed to behaving additively [3]. However, it must be emphasized that we cannot infer that a disorder or trait is necessarily genetically influenced simply because it is familial. Traits that are almost certainly influenced by multiple factors, for example, career choice, may show a very high 'relative risk' and can even mimic Mendelian inheritance [1]. To tease apart the effects of genes and shared family environmental influences, we need to perform twin or adoption studies.

An important fundamental issue in family studies is what measure do we use for the proportion of relatives affected? The simplest answer is to use the lifetime **prevalence** of the disorder. That is, the number of family members who have ever been affected divided by the total number. However, a complication arises because complex disorders tend to have their first onset over a range of ages, a so-called period of risk. For adult onset disorders, some family members under investigation may not yet have entered the period of risk; others may have lived through the entire period without becoming affected, while others who are unaffected will still be within the period of risk. Clearly, only those who remain unaffected after having passed through the entire risk period can be classed as definitely unaffected. Therefore, lifetime prevalence underestimates the true lifetime risk

2 Family Study and Relative Risk

of the disorder. This problem can be addressed using an age correction, the most straightforward of which, originally proposed by Weinberg (the same Weinberg after whom the Hardy Weinberg equilibrium in population genetics is named) is to calculate a corrected denominator or *bezugsziffer* (BZ). The lifetime risk or morbidity risk (MR) of the disorder can be estimated as the number of affecteds (A) divided by the BZ, where the BZ is calculated as:

$$\sum_i w_i + A$$

and where w_i is the weight given to the i th unaffected individual on the basis of their current age. The simplest system of assigning weights, the shorter Weinberg method, is to give the weight of zero to those younger than the age of risk, a weight of a half to those within the age of risk, and weight of one to those beyond the age of risk. A more accurate modification devised by Erik Strömberg is to use an empirical age of onset distribution from a large separate sample, for example, a national registry of psychiatric disorders, to obtain the cumulative frequency of disorder over a range of age bands from which weights can be derived [4]. Unfortunately, national registry data are often unavailable and an alternative method is to take the age of onset distribution in the probands and transform it to a normal distribution, for example, using a log transform [2]. The log age for each unaffected relative can be converted to a standard score and a weight, the proportion of the period a risk that has been lived through, can be assigned by reference to the standard normal integral.

Another approach is to carry out life table analysis. The method most often used in family studies is called the *Weinberg morbidity table*, but essentially the method is the same as in the life table analysis performed in other spheres. The distribution of

survival times (or times to becoming ill) is divided into a number of intervals. For each of these, we can calculate the number and proportion of subjects who entered the interval unaffected and the number and proportion of cases that became affected during that interval, as well as the number of cases that were lost to follow-up (because they had died or had otherwise 'disappeared from view'). On the basis of these numbers and proportions, we can calculate the proportion 'failing' or becoming ill over a certain time interval that is usually taken as the entire period of risk. A further alternative is to use a Kaplan Meier product limit estimator. This allows us to estimate the survival function (*see Survival Analysis*) directly from continuous survival or failure times instead of classifying observed survival times into a life table. Effectively, this means creating a life table in which each time interval contains exactly one case. It therefore has an advantage over a life table method in that the results do not depend on grouping of the data.

Fechner, Gustav T

Born: April 19, 1801, in Gross Särchen, Germany.

Died: November 18, 1887, in Leipzig, Germany.

October 22 is celebrated as Fechner Day – the day in 1850 on which he claimed to have had the insight now known as Fechner’s Law: that is, that sensation increases as the logarithm of the stimulus intensity. However, his main contributions to statistics lie elsewhere.

Gustav Theodor Fechner was the second of five children of a Lutheran pastor, who died when he was 5 years old. He went to live with his uncle, also a pastor, and attended several schools. In 1817, he enrolled on a medical course at the University of Leipzig, obtaining his masters degree and title of doctor in 1823. One of his lecturers was E. H. Weber, after whom Fechner named Weber’s Law. Fechner stayed on in Leipzig to study physics and mathematics, and earned some money translating French science textbooks into German. He was appointed a lecturer in physics in 1824, professor in 1831, and given the professorial chair in 1834. He published many important physics papers. Fechner married A. W. Volkmann’s sister, Clara Maria, in 1833. He resigned his chair in 1840, because he had become ill, perhaps through overwork. He had also damaged his eyes, through staring at the sun for his research on subjective colors. He became reclusive, and turned his mind to philosophical and religious problems. In 1851, he published the *Zend-Avesta*, a philosophical work about the relation between mind and matter, which he regarded as two aspects of the same thing. The appendix to this book contained his program of psychophysics and a statement of his law (see [2]). He then undertook measurements of the Weber fraction to support his own law. He used his training in physics to develop three psychophysical test methods, and to give mathematical formulae for his theories. In 1860, he published his main psychophysical work, the *Elemente der Psychophysik* [3], only the first volume of which has

been translated [1]. The book influenced contemporary physiologists, who then investigated Weber’s Law in several senses. Fechner himself turned his attention to experimental aesthetics, which he studied from 1865 to 1876. He returned to psychophysics to answer some criticisms, publishing his *Revision* in 1882. He was a founder member of the Royal Saxon Academy of Sciences in 1846.

Fechner was a wide-ranging author, even writing satirical material under the pseudonym of Dr. Mises. From the point of view of statisticians, his main contributions lie in the development of probabilistic test procedures for measuring thresholds and in the associated mathematics. He used probability theory in the ‘Method of Right and Wrong Cases’, applying Gauss’s normal distribution of errors. He took h , the measure of precision, as an inverse measure of the differential threshold [$h = 1/(\sigma\sqrt{2})$]. He wrote several papers on statistics, but his important unfinished book on the topic, *Kollektivmasslehre* [*Measuring Collectives*] [4], was not published till 10 years after his death. Fechner believed in indeterminism, but reconciled this with the laws of nature through the statistics of probability distributions: distributions are lawful, while individual phenomena are not (see [5]). He also argued that some distributions were asymmetrical, a novel idea at the time. However, Fechner’s statistics never achieved the lasting fame of his psychophysical law.

Field Experiment

Experimental research studies are used when the researcher wishes to make causal inferences about the variables under investigation. Such studies can be designed to have high **internal validity**. Because of the controlled nature of the research, they may have weak **external validity**, that is, the results do not generalize to other individuals or settings. Sometimes, the experimental studies are criticized for being laboratory studies where the setting is artificial, because the subjects know that they are being studied, the researcher does not behave in a natural manner, and subjects may react to the researcher in an unnatural manner when they are not able to forget that they are participating in an experiment. Such studies may lack ecological validity, because participants are observed for what they can do and not what they would do normally. Other threats to external validity include volunteer bias, mortality effects, and a limited population. Finally, the results of laboratory experiments may be so limited that they can be found only by exact replication of the design.

If the above limitations to the laboratory study are of concern to the researcher and external validity is desired, then the study may be performed in the real world or a natural setting and includes the procedures of an experiment, that is, random assignment of participants to treatments or conditions, manipulated levels of the independent variable, control of extraneous variables, and reliable and valid measurement of the dependent variable. Such research investigations are called (randomized) field experiments.

As an example of a field study, consider the randomized experiment of Comer's School Development Program conducted in 23 middle schools in Prince George's County, Maryland [4]. The study was conducted over 4 years with 23 middle schools of which 21 were matched on the basis of racial composition and achievement test scores for 2 years prior to the study. These schools were assigned randomly to program or comparison status using a coin toss. The two additional schools were pilot program sites for a year before the study began. They were included as program schools, because no difference was found when these two schools were included or excluded from the analyses with the other 21 schools, which resulted in 13 experimental schools and 10 control schools. Repeated measurements were made with more than

12,300 students and 2000 staff, 1000 parents were surveyed, and schools records were accessed in the study. The middle-school program in Prince George's County is a 2-year one, which resulted in three cohorts of students. Even with the initial matching of schools on racial composition and achievement test scores, data were adjusted on the basis of three school-level covariates: the average socioeconomic status of students, their average elementary school California Achievement Test, and school size. The covariate adjustments served to reduce the error and not to correct initial bias, given the random assignment employed at the beginning of the study.

This study incorporated the elements of an experiment that resulted in internal validity, with its random assignment of Comer's School Development Program to schools, controlled extraneous variables by the matching of schools and the adjustments based on covariates, and measured the dependent variables in a reliable, sensitive, and powerful manner. Data were analyzed using **multiple linear regression**, school-level **multivariate analysis of variance**, school-level **analysis of variance**, and correlational analyses (*see Correlation Studies*). When results were statistically significant, magnitude of the effect was obtained. Because Cook et al. [4] conducted a field experiment, they were able to conclude that their findings apply to common, realistic situations and actually reflect natural behaviors.

Two examples of field experiments that employed selection are Tennessee's Project STAR, which involved an investigation into reduction in class size [8], and the Milwaukee Parental Choice Program that tested the use of school vouchers with a random selection of participants when there were more applicants to a particular school and grade than could be accommodated [9]. In the 1985–1986 school year, Project STAR included 128 small classes (of approximately 1900 students), 101 regular classes (of approximately 2300 students), and 99 regular classes with teacher aides (of approximately 2200 students). Details regarding the political and institutional origins of the randomized controlled trial on elementary-school class-size design can be found in Ritter and Boruch [8].

Not all field experiments involve such large numbers. Fuchs, Fuchs, Karns, Hamlett, and Katzaroff [5]

2 Field Experiment

examined the effects of classroom-based performance-assessment-driven instruction using 16 teachers who were assigned randomly to performance-assessment and nonperformance-assessment conditions. All of the teachers had volunteered to participate. Neither the teachers nor their classes were matched, but Fuchs et al. used inferential statistics to indicate that the teachers in the two conditions were comparable on demographic variables of years of teaching, class size, ethnicity, and educational level. Teachers completed a demographic information form reporting on information about each student in the class. Results of statistical tests revealed that the groups were comparable. Although the researchers were not able to control extraneous variables, they tested to assess whether extraneous variables could affect the outcome of the research.

Field experiments can be conducted with the general public and with selected groups. Each of these two types of studies with the general public has certain limitations. Field experiments that are conducted in an unrestricted public area in order to generalize to the typical citizen generally are studying social behaviors. Such investigations if conducted as laboratory experiments would reduce the reliability and validity of the results. The experiments with the general public generally are carried out in one of two ways: individuals can be targeted and their responses observed to a condition of an environmental independent variable or the researcher or a confederate creates a condition by approaching the public and exhibiting a behavior to elicit a response. Some of the limitations of field studies with the public are that the situations are contrived, external validity is limited to situations similar to those in the study, and random selection is not possible in that the sample is a convenient one depending on the individuals who are present in the location at the time of the study. Albas and Albas [1] studied personal-space behavior while conducting a fictitious poll by measuring how far the participant would stop from the pollster. They manipulated the factors of the meeting occurring in the safety of a shopping mall versus a less safe city park and of whether the pollster made eye contact or did not because of wearing dark glasses.

The other approach to field experiments involves studying a specific group of participants that exists already. Some examples would be studying young children at a day-care center or elderly individuals at a senior center. Sometimes the researcher is not

able to disguise the study, especially if the researcher must provide instructions; other times the researcher is able to act unobtrusively. For example, if there is a one-way mirror at the day-care center, the researcher may be able to view the behavior of the children without their knowing that they are being observed. If teachers or supervisors will be serving as the researcher, they should be given explicit training, and the researcher should use a double-blind procedure. A double-blind procedure was used in the 1954 field trial of the Salk poliomyelitis vaccine. Both the child getting the treatment and the physician who gave the vaccine and evaluated the outcome were kept in ignorance of the treatment given [7].

Several references that can be consulted for additional details regarding field experiments are [2], [3], and [10]. Kerlinger [6], in his second edition, has a detailed discussion with examples of field experiments and field studies (see **Quasi-experimental Designs**).

Finite Mixture Distributions

Early in the 1890s, Professor W.R. Weldon consulted statistician **Karl Pearson** about a set of measurements on the ratio of forehead to body length for 1000 crabs. A plot of the data (see Figure 1) showed that they were skewed to the right. Weldon suggested that the reason for this skewness might be that the sample contained representatives of two types of crabs, but, when the data were collected, they had not been labeled as such. This led Pearson to propose that the distribution of the measurements might be modeled by a weighted sum of two *normal distributions* (see **Catalogue of Probability Density Functions**), with the two weights being the proportions of the crabs of each type. This appears to be the first application of what is now generally termed a *finite mixture distribution*.

In mathematical terms, Pearson's suggestion that the distribution for the measurements on the crabs was of the form

$$f(x) = pN(x, \mu_1, \sigma_1) + (1 - p)N(x; \mu_2, \sigma_2) \quad (1)$$

where p is the proportion of a type of crab for which the ratio of forehead to body length has mean μ_1 and standard deviation σ_1 , and $(1 - p)$ is the proportion of a type of crab for which the corresponding values are μ_2 and σ_2 . In equation (1)

$$N(x; \mu_i, \sigma_i) = \frac{1}{\sqrt{2\pi}\sigma_i} \exp\left[-\frac{1}{2\sigma_i^2}(x - \mu_i)^2\right] \quad (2)$$

The distribution in (1) will be bimodal if the two component distributions are widely separated or will simply display a degree of skewness when the separation of the components is not so great.

To fit the distribution in (1) to a set of data, its five parameters, $p, \mu_1, \sigma_1, \mu_2, \sigma_2$ have to be estimated from the data. Pearson, in his classic 1894 paper [10], devised a method that required the solution of a ninth-degree polynomial, a task (at the time) so computationally demanding that it lead Pearson to state

'the analytic difficulties, even for a mixture of two components are so considerable that it may be

questioned whether the general theory could ever be applied in practice to any numerical case'.

But Pearson did manage the heroic task of finding a solution, and his fitted two-component normal distribution is shown in Figure 1, along with the solution given by **maximum likelihood estimation** (see later), and also the fit given by a single normal distribution.

Estimating the Parameters in Finite Mixture Distributions

Pearson's original estimation procedure for the five parameters in (1) was based on the *method of moments*, but is now only really of historical interest (see **Estimation**). Nowadays, the parameters of a simple finite mixture model such as (1) or more complex examples with more than two components, or other than univariate normal components, would generally be estimated using a maximum likelihood approach, often involving the *EM algorithm*. Details are given in [4, 9, and 12].

In some applications of finite mixture distributions, the number of components distributions in the mixture is known *a priori* (this was the case for the crab data where two types of crabs were known to exist in the region from which the data were collected). But, finite mixture distributions can also be used as the basis of a *cluster analysis* of data (see **Hierarchical Clustering; k-means Analysis**), with each component of the mixture assumed to describe the distribution of the measurement (or measurements) in a particular cluster, and the maximum value of the estimated *posterior probabilities* of an observation being in a particular cluster being used to determine cluster membership (see [4]). In such applications, the number of components of the mixture (i.e., the number of clusters in the data) will be unknown and therefore will also need to be estimated in some way. This difficult problem is considered in [4 and 9] and see **Number of Clusters**.

Some Examples of the Application of Finite Mixture Distributions

A sex difference in the age of onset of schizophrenia was noted in [6]. Subsequently, it has been found to

Figure 1 Frequency polygon of ratio of forehead to body length in 1000 crabs and fitted mixture and single normal distributions

be one of the most consistent findings in the epidemiology of the disorder. Levine [7], for example, collated the results of 7 studies on the age of onset of the illness, and 13 studies on age at first admissions, and showed that all these studies were consistent in reporting an earlier onset of schizophrenia in men than in women. Levine suggested two competing models to explain these data:

The timing model states that schizophrenia is essentially the same disorder in the two sexes, but has an early onset in men and a late onset in women ... In contrast with the timing model, the subtype model posits two types of schizophrenia. One is characterized by early onset, typical symptoms, and poor premorbid competence, and the other by late onset, atypical symptoms, and good premorbid competence ... the early onset typical schizophrenia is largely a disorder of men, and late onset, atypical schizophrenia is largely a disorder in women.

The subtype model implies that the age of onset distribution for both male and female schizophrenics

will be a mixture, with the mixing proportion for early onset schizophrenia being larger for men than for women. To investigate this model, finite mixture distributions with normal components were fitted to age of onset (determined as age on first admission) of 99 female and 152 male schizophrenics using maximum likelihood. The data are shown in Table 1 and the results in Table 2. **Confidence intervals** were obtained by using the *bootstrap* (see [2] and **Bootstrap Inference**). The bootstrap distributions for each parameter for the data on women are shown in Figure 2.

Histograms of the data showing both the fitted two-component mixture distribution and a single normal fit are shown in Figure 3.

For both sets of data, the *likelihood ratio test* for number of groups (see [8, 9], and **Maximum Likelihood Estimation**) provides strong evidence that a two-component mixture provides a better fit than a single normal, although it is difficult to draw convincing conclusions about the proposed subtype model of schizophrenia because of the very wide

Identifying Activated Brain Regions

In [3], an experiment is reported in which functional magnetic resonance imaging (fMRI) data were collected from a healthy male volunteer during a visual stimulation procedure. A measure of the experimentally determined signal at each voxel in the image was calculated, as described in [1]. Under the null hypothesis of no experimentally determined signal change (no activation), the derived statistic has a chi-square distribution with two degrees of freedom (see **Catalogue of Probability Density Functions**). Under the presence of an experimental effect (activation), however, the statistic has a noncentral chi-squared distribution (see [3]). Consequently, it follows that the distribution of the statistic over all voxels in an image, both activated and nonactivated, can be modeled by a mixture of those two component densities (for details, again see [3]). Once the parameters of the assumed mixture distribution have been estimated, so can the probability of each voxel in the image being activated or nonactivated. For the visual simulation data, voxels were classified as ‘activated’ if their posterior probability of activation was greater than 0.5 and ‘nonactivated’ otherwise. Figure 4 shows the ‘mixture model activation map’

Figure 2 Bootstrap distributions for five parameters of a two-component normal mixture fitted to the age of onset data for women: (a) mixing proportion; (b) mean of first distribution; (c) standard deviation of first distribution; (d) mean of second distribution; (e) standard deviation of second distribution

Figure 3 Histograms and fitted mixture distributions for age of onset data for women and men

of the visual simulation data for selected slices of the brain (activated voxels indicated).

Finite mixture models are now widely used in many disciplines. In psychology, for example, latent class analysis, essentially a finite mixture with multivariate Bernoulli components (*see Catalogue of Probability Density Functions*), is often used as a categorical data analogue of **factor analysis**. And, in medicine, mixture models have been successful in analyzing *survival times* (*see* [9] and **Survival Analysis**). Many other applications of finite mixture distributions are described in the comprehensive account of finite mixture distributions given in [9].

Software for Fitting Finite Mixture Distributions

The following sites provide information on software for mixture modeling:

NORMIX was the first program for clustering data that consists of mixtures of multivariate Normal distributions. The program was originally written John H. Wolfe in the 1960s [13]. A version that runs under MSDOS-Windows is available as freeware at <http://alumni.caltech.edu/~wolfe/normix.htm>.

Geoff McLachlan and colleagues have developed the EMMIX algorithm for the automatic fitting and testing of normal mixtures for multivariate data (*see* <http://www.maths.uq.edu.au/~gjm/>).

A further program is that developed by Jorgensen and Hunt [5] and the source code is available from Murray Jorgensen's website (<http://www.stats.waikato.ac.nz/Staff/maj.html>).

Fisher, Sir Ronald Aylmer

Born: February 17, 1890, in London, England.

Died: July 29, 1962, in Adelaide, Australia.

In Cambridge, in the late 1920s, a group of University dons and their wives and guests sat for afternoon tea. One woman asserted that the taste of tea depended on whether the milk was added to the cup before or after the tea. While the academics put the proposition down as sheer nonsense, a short, bearded man by the name of Ronald Fisher set about putting it to the test. This tale and its implications for statistics and experimentation are well documented (see [2, 3, 8]); however, it unveils much about Fisher as a person. He was a man fascinated by discovery and science. As well as being ‘perhaps the most original mathematical scientist of the (last) century’ (Efron, in [9, p. 483], he published widely on genetics, biology (notably inbreeding), and medicine (the links between smoking and cancer). Even within the domain of statistics, his interests were wide: Barnard [1, p. 162] concluded that ‘apart from the work done on multivariate problems . . . Fisher left little here for others to do’. For many, Fisher laid the foundations of modern statistics [1, 11].

Fisher was born in London in 1890, and after an education at Harrow public school, studied mathematics at Caius College, Cambridge, from where he graduated with the prestigious title of a Wrangler (the highest honor in mathematics) in 1912. He stayed at Cambridge to study physics following which he had a succession of jobs (the Mercantile and General investment Company, a farm in Canada, and a school teacher) before taking up a post at the Rothamsted Experimental Station in 1919. Although Fisher published several key papers during his time as a school teacher (including that on the distributional properties of the correlation coefficient), it was at Rothamsted that he produced his famous series of ‘Studies in Crop Variation’ in which he developed the **analysis of variance** and **analysis of covariance** and explored the importance of **randomization** in experimentation. In 1933, he became the Galton Professor of Eugenics at University College, London following **Karl Pearson’s** retirement; then in 1943 he became the Arthur Balfour Professor of Genetics at Cambridge University.

He retired in 1957, and in 1959 settled in Adelaide, Australia. His honors include being elected Fellow of the Royal Society (1929), the Royal Medal (1938), the Darwin Medal (1948), the Copley Medal (1955), and a knighthood (1952) (see [4] for an extensive biography).

Savage [9] suggests that it would be easier to list the areas of statistics to which Fisher took no interest, and this is evidenced by the breadth of his contributions. Savage [9] and Barnard [1] provide thorough reviews of Fisher’s contributions to statistics, but his most well known are in the development of (1) sampling theory and significance testing; (2) estimation theory (he developed **maximum likelihood estimation**); and (3) multivariate techniques such as Fisher’s **discriminant function analysis**. In addition, through his development of experimental designs and their analysis, and his understanding of the importance of randomization, he provided a scientific community dominated by idiosyncratic methodological practices with arguably the first blueprint of how to conduct research [8].

Although some have noted the similarities between aspects of Fisher’s work and his predecessor’s (for example, Stigler, [10], notes similarities with Francis Edgeworth’s work on analysis of two-way classifications and maximum likelihood estimators), Fisher’s contributions invariably went well beyond those earlier sources (see [9]). His real talent was in his intuition for statistics and geometry that allowed him to ‘see’ answers, which he regarded as obvious, without the need for mathematical proofs (although invariably the proofs, when others did them, supported his claims). This is not to say that Fisher was not a prodigious mathematician (he was); however, it did mean that, even when connected to other’s earlier work, his contributions had greater clarity and theoretical and applied insight [5].

Much is made of Fisher’s prickly temperament and the public disagreements he had with Karl Pearson and **Jerzy Neyman**. His interactions with Pearson got off on the wrong foot when Pearson published Fisher’s paper on the distribution of **Galton’s** correlation coefficient but added an editorial, which, to the casual reader, belittled Fisher’s work. The footing became more unstable when two years later Pearson’s group published extensive tables of this distribution without consulting Fisher [5]. Their relationship remained antagonistic with Fisher publishing ‘improvements’ on Pearson’s ideas, and Pearson

referring in his own journal to apparent errors made by Fisher [8]. With Neyman, the rift developed from a now infamous paper delivered by Neyman to the Royal Statistical Society that openly criticized Fisher's work [7]. Such was their antagonism that Neyman openly attacked Fisher's factorial designs and ideas on randomization in lectures while they both worked at University College, London. The two feuding groups even took afternoon tea (a common practice in the British academic community of the time) in the same room but at different times [6]. However, these accounts portray a one-sided view of all concerned, and it seems fitting to end with Irwin's (who worked with both K. Pearson and Fisher) observation that 'Fisher was always a wonderful conversationalist and a good companion. His manners were informal . . . and he was friendliness itself to his staff and any visitors' ([5, p. 160]).

Fisherian Tradition in Behavioral Genetics

R.A. Fisher was a major figure in both mathematics and biology: besides his major contribution to statistics he was greatly respected by other mathematicians. Through his applications of statistical theory to biology, Fisher achieved the integration of genetics¹ with evolution, which was the keystone of the evolutionary synthesis [15]. For three decades after the rediscovery in 1901 of the work of Mendel, enthusiastic supporters had felt that ‘Mendelism’ invalidated Darwin’s adoption of natural selection as the main mechanism of evolution. This was overthrown by Fisher’s demonstration that, on the contrary, Mendelian genetics provides both the source of appropriate variation on which selection can act, and the means for conserving and accumulating these favorable variations in the population.

Since the synthesis, most biologists, behavior scientists, in particular, have been more Darwinian than Darwin. Though modern geneticists are busy with postgenomic opportunities² to discover how specific genes actually exert their effects upon development and metabolism, and often take evolution for granted as a purely historical explanation, the logic of selection at the level of the gene offers important insights into such phenomena as genomic imprinting [19] and aging [4]. However, it is in the field of behavior that the pioneering work of Fisher has facilitated major advances in understanding. It has provided the heady theoretical underpinning of sociobiology [21] and its more politically correct descendant, evolutionary psychology [3]. Fisher’s contribution to the sister science of behavior genetics per se³ [18] was in quantitative genetics, particularly in the part played by estimating degrees of relatedness [12].

Fisher [13] powerfully analyzed the logical difficulties inherent for Darwin in his acceptance of blending inheritance. This assumed that the offspring of any novel variant would be more nearly a fusion of the variant and the other parent of normal type, with the problem that after a very few generations all trace of that variation would be lost. In such a situation, natural selection could not take hold. Darwin noted [6] that variation was greater in domesticated species, and thought this must

be due to novel environmental effects in captivity, though the undiminished variance of ancient domestic breeds implied the implausible requirement of a long history of continuously new environmental factors. He knew, of course, through his study of artificial selection, that dramatic transformation analogous to natural evolution could be produced in these varying domestic animals. Wild populations would only match this, and be especially subject to natural selection, in situations where they had entered markedly novel environments, or big changes had come about having similar effects to those of the environments of domestication. This rather went against Darwin’s conviction that evolution occurred through the very gradual and continuous accumulation of tiny changes.

The particulate theory of Mendelism explains how novelties, however they may arise initially, are not lost in the population, but appear perennially (unless natural selection takes a hand). The Hardy–Weinberg equation was used (but not referenced) by Fisher [13] to clarify this point. If two alternative alleles exist, one with a frequency of p in the gene pool, and the other with the complementary frequency of q (where $p + q = 1$), then the three genotypes resultant from random matings of individuals carrying these alleles in a large population will inexorably be in the ratios corresponding to the three terms of the equation:

$$p^2 + 2pq + q^2$$

with p^2 as the frequency of the homozygote for p , pq for the heterozygote, and q^2 for the homozygote for q .

Against this understood background, even slight selective advantages will produce gradual directional shifts, the ‘tiny wedges’ beloved of Darwin. The flamboyant variance of domestic species can be accounted for by the higher chances of survival of mutations that would be much less readily weeded out than in a natural population, together with their often positive promotion by artificial selection (like the ‘appealing’ features of many rather monstrous breeds of dogs, for example).

As for the notion, supported by De Vries, Bateson, and the mutationist Mendelians, that mutation could somehow drive evolution, Fisher lists the possible hypothetical mechanisms through which this might operate, for which no evidence exists, and most of which are inherently implausible. Even Weissman’s

notion that once mutations in a certain direction occurred, it was more likely that further ones in the same direction would follow, is shown to be redundant (and incorrect).

Fisher was fond of comments such as ‘Natural selection is a mechanism for generating an exceedingly high degree of improbability’ [11]. Now the idea of evolution being due to natural selection acting on mutations occurring by chance was repellent to many critics from the publication of Darwin’s *Origin of Species* [5]. Fisher explained, however, that this did not resemble an extraordinary run of good luck such as every client of a casino wishes he might enjoy, but the inexorable workings of the laws of chance over a longer sample upon which the profitability of such establishments depends. Just as Mendel had been influenced by the physicist von Ettinghausen to apply combinatorial algebra to his breeding experiments, so a postdoctoral year at Cambridge with James Jeans⁴ (after his Mathematics degree there) enthused Fisher with Maxwell’s statistical theory of gases, Boltzmann’s statistical thermodynamics, and quantum mechanics. He looked for an integration in the new physics of the novelty generation of biological evolution and the converse principle of entropy in nonliving systems [10].

Alongside these adjustments to post-Newtonian science, transcending the Newtonian scientific world view of Darwin, Fisher was in a sense the grandson of Darwin (see [10]), for he was much influenced by two of Charles’s sons, Horace, and particularly Leonard. This must have been very exciting to a young middle-class man who might just as well have taken a scholarship in biology at Cambridge, and took as the last of his many school prizes the complete set of Darwin’s books which he read and reread throughout his life, and with Leonard in particular he interchanged many ideas and was strongly encouraged by him. Now both these sons of such a renowned father and from such a prominent family were involved in the eugenics movement to which Fisher heartily subscribed⁵. There is a lot of this in the second half of his *The Genetical Theory of Natural Selection*. It is not clear how the logical Fisher reconciled his attachment to Nietzsche’s ideas of superior people who should endeavor to generate lots of offspring and be placed ‘beyond good or evil,’ with his stalwart adherence to Anglicanism⁶, but he certainly practiced what he preached by in

due course fathering eight children on his 17-year-old bride. There is inflammable material here for those whose opposition to sociobiology and evolutionary psychology is colored by their political sensitivity to the dangerous beasts of Nazism and fascism forever lurking in human society.

In his population genetics, Fisher shifted the emphasis from the enhanced chances of survival of favored individuals to the study, for each of the many alleles in a large population, of the comparative success of being duplicated by reproduction. In this calculus, alleles conferring very slight benefits (to their possessor) in terms of Darwinian fitness⁷ would spread in the gene pool at the expense of alternative alleles. This gave rise to important theoretical advances that were particularly influential in the study of behavior. The adaptive significance of the minutiae of behavior could in principle be assessed in this way, and in some cases measured in the field with some confidence about its validity. When Fisher was back in Cambridge as Professor of Genetics, one of his most enthusiastic students was William Hamilton, who from this notion of the gene as the unit of selection, derived inclusive fitness theory [14], popularly expounded by Richard Dawkins in [9] and a series of similar books. Expressing Fisher’s [12] degrees of genetic resemblance between closer and more distant relatives in terms of the probability, r , of a rare gene in one individual also occurring in a relative, Hamilton propounded that for an apparently altruistic social action, in which an actor appears to incur a cost C (in terms of Darwinian fitness) in the course of conferring a benefit B to a relative, the following equation applies:

$$rB - C > 0$$

This has become known as Hamilton’s rule, and it means that an allele predisposing an animal to help a relative will tend to spread if the cost to the ‘donor’ is less than the benefit to the recipient, downgraded by the degree of relatedness between the two.

This is because r is an estimate of the chances that the allele will indirectly make copies of itself via the progeny of the beneficiary, another way of spreading in the gene pool. This is also known as kin selection.

Robert Trivers [20] soon followed this up with the notion of reciprocal altruism in which similar altruistic acts could be performed by a donor for an unrelated recipient, provided that the cost was

small in relation to a substantial benefit, if the social conditions made it likely that roles would at some future time be liable to be reversed, and that the former recipient could now do a favor for the former donor. This would entail discrimination by the individuals concerned between others who were and others who were not likely to reciprocate in this way (probably on the basis of memory of past encounters). There are fascinating sequelae to these ideas, as when the idea of ‘cheating’ is considered, which Trivers does in his benchmark paper [20]. Such a cozy mutual set-up is always open to exploitation, either by ‘gross’ cheaters, who are happy to act as beneficiaries but simply do not deliver when circumstances would require them to act as donors, or by more subtle strategists who give substandard altruism, spinning the balance of costs and benefits in their own favor. These provide fertile ground for cheater-detection counter measures to evolve, an escalating story intuitively generative of many of the social psychological features of our own species.

The pages of high quality journals in animal behavior (such as *Animal Behaviour*) are today packed with meticulous studies conducted in the field to test the ideas of Hamilton and Trivers, and a corresponding flow of theoretical papers fine-tuning the implications.

Another key idea attributed to Fisher is the ‘run-away theory’ of sexual selection. This concerns male adornment, and Darwin’s complementary notion of female choice, long treated with skepticism by many, but now demonstrated across the animal kingdom. If it comes about that a particular feature of a male bird, for example, such as a longer than usual tail, attracts females more than tails of more standard length (which in some species can be demonstrated by artificial manipulation [1]), and both the anatomical feature and the female preference are under genetic control, then the offspring of resultant unions will produce sexy sons and size-sensitive females who in turn will tend to corner the mating market. This is likely to lead, according to Fisher [13], to further lengthening of the tail and strengthening of the preference, at an exponential rate, since the greater the change, the greater the reproductive advantage, so long as this is not outweighed by other selective disadvantages, such as dangerous conspicuousness of the males. Miller [17] has inverted this inference, and from fossil data supporting such a geometric increase

in brain size in hominids, has speculated that a major influence on human evolution has been because of the greater attractiveness to females of males with larger brains enabling them to generate a more alluring diversity of courtship behaviors. Other explanations, either alternative or complementary, have also been forwarded for the evolution of flamboyant attraction devices in male animals [22].

The evolutionary stabilization of the sex ratio – that except under special circumstances the proportion of males to females in a population will always approximate to 1 : 1 – is another fecund idea that has traditionally been attributed to Fisher. Actually the idea (like many another) goes back to Darwin, and to *The Descent of Man*. Like many of us Fisher possessed (and read and reread) the Second Edition of this book [8] in which Darwin backtracks in a quote I would have been critical of were it to occur in a student’s essay today⁸:

‘I formerly thought that when a tendency to produce the two sexes in equal numbers was advantageous to the species, it would follow from natural selection, but I now see that the whole problem is so intricate that it is safer to leave its solution for the future’ [8] (pp. 199–200).

Fisher [13] also quotes this, but gives an incorrect citation (there are no references in his book) as if it were from the first edition. In the first edition [7], Darwin does indeed essay ways in which the sex ratio might come under the influence of natural selection. He does not rate these effects of selection as a major force compared with ‘unknown forces’:

‘Nevertheless we may conclude that natural selection will always tend, though sometimes inefficiently, to equalise the relative numbers of the two sexes.’ [ibid. Vol. I, p. 318]

Then Darwin acknowledges Herbert Spencer, not for the above, but for the idea of what we would now call the balance between *r* and *K* selection. Darwin is unclear how fertility might be reduced by natural selection once it has been strongly selected, for direct selection, by chance, would always favor parents with more offspring in overpopulation situations, but the cost of producing more, to the parents, and the likely lower quality of more numerous offspring, would be ‘indirect’ selective influences reducing fertility in severely competitive conditions.

There is an anticipation here too of **Game Theory** which was developed by the late, great successor to Fisher as the (on one occasion self-styled!) ‘Voice of Neodarwinism’, John Maynard Smith [16]. The relevance of game theory is to any situation in which the adaptive consequences (Darwinian fitness) of some (behavioral or other) characteristic of an individual depend, not only on the environment in general, but upon what variants of this other members of the same species possess. Put succinctly, your best strategy depends on others’ strategies⁹. In the case of the sex ratio, if other parents produce lots of daughters, it is to your advantage to produce sons. In the case of sexual selection, if males with long tails are cornering the mating market, because females with a preference for long tails are predominant, it is to your advantage to produce sons with even longer tails. The combination of some of the theories here mentioned, such as game theory and the principle of reciprocal altruism [2] is an index of the potential of the original insights of Fisher. Iterative computer programs have made such subtle interactions easier to predict, and fruitfully theorize about than the unaided though brilliant mathematics of Fisher.

Notes

1. ‘Genetics, the study of the hereditary mechanism, and of the rules by which heritable qualities are transmitted from one generation to the next...’ Fisher, R.A. (1953) Population genetics (The Croonian Lecture). *Proceedings of the Royal Society, B*, 141, 510–523.
2. Work made possible by the delineation of the entire genome of mice and men and an increasing number of other species.
3. For sociobiology and evolutionary psychology, some degree of a hereditary basis for behavior is axiomatic. Behavior genetics seeks to demonstrate and analyze specific examples of this, both in animal breeding experiments and human familial studies, for practical as well as theoretical purposes.
4. It was Jeans who was once asked whether it was true that he was one of the only three people to understand relativity theory. ‘Who’s the third’? he allegedly asked.
5. I cherish the conviction that Charles was entirely egalitarian.
6. While Nietzsche clearly recognized Christian values as in direct opposition to his own.
7. Measured as the number of fertile offspring an individual produces which survive to sexual maturity.
8. The troublesome phrase here is ‘advantageous to the species.’ The point about the action of selection here is that it is the advantage to the genes of the individual that lead it to produce more male or more female offspring.
9. There can be interactions between species as well, as for example in arms races, for example, selection for ever increasing speed both of predator and prey in say cheetahs hunting antelope.

Fixed and Random Effects

In the specification of multilevel models (*see Linear Multilevel Models*), as discussed in [1] and [3], an important question is which explanatory variables (also called *independent variables* or *covariates*) to give random effects. A quantity being random means that it fluctuates over units in some population; and which particular unit is being observed depends on chance. When some effect in a statistical model is modeled as being random, we mean that we wish to draw conclusions about the population from which the observed units were drawn rather than about these particular units themselves.

The first decision concerning random effects in specifying a multilevel model is the choice of the levels of analysis. These levels can be, for example, individuals, classrooms, schools, organizations, neighborhoods, and so on. Formulated generally, a level is a set of units, or equivalently a system of categories, or a classification factor in a statistical design. In statistical terminology, a level in a multilevel analysis is a design factor with random effects. What does this mean?

The main point of view that qualifies a set of units, for example, organizations, as a level in the multilevel sense is that the researcher is not primarily interested in the particular organizations (units) in the sample but in the population (the wider set of organizations) for which the observed units are deemed to be representative. Statistical theory uses the word ‘exchangeability’, meaning that from the researcher’s point of view any unit in the population could have taken the place of each unit in the observed sample. (Whether the sample was drawn randomly according to some probability mechanism is a different issue – sometimes it can be argued that convenience samples or full population inventories can reasonably be studied as if they constituted a random sample from some hypothetical larger population.) It should be noted that what is assumed to be exchangeable are the residuals (sometimes called *error terms*) associated with these units, which means that any fixed effects of explanatory variables are already partialled out.

In addition, to qualify as a nontrivial level in a multilevel analysis, the dependent variable has to show some amount of residual, or unexplained, variation, associated with these units: for example, if the

study is about the work satisfaction (dependent variable) of employees (level-one units) in organizations (level-two units), this means that employees in some organizations tend to have a higher satisfaction than in some other organizations, and the researcher cannot totally pin this down to the effect of particular measured variables. The researcher being interested in the population means here that the researcher wants to know the amount of residual variability, that is, the residual variance, in average work satisfaction within the population of organizations (and perhaps also in the more complicated types of residual variability discussed below). If the residual variance is zero, then it is superfluous to use this set of units as a level in the multilevel analysis.

A next decision in specifying a multilevel model is whether the explanatory variables considered in a particular analysis have fixed or random effects. In the example, such a variable could be the employee’s job status: a level-one variable, since it varies over employees, the level-one units. The vantage point of multilevel analysis is that the effect of job status on work satisfaction (i.e., the regression coefficient of job level) could well be different across organizations. The fixed effect of this variable is the average effect in the entire population of organizations, expressed by the regression coefficient. Since mostly it is not assumed that the average effect of an interesting explanatory variable is exactly zero, almost always the model will include the fixed effect of all explanatory variables under consideration. When the researcher wishes to investigate differences between organizations in the effect of job level on work satisfaction, it will be necessary to specify also a random effect of this variable, meaning that it is assumed that the effect varies randomly within the population of organizations, and the researcher is interested in testing and estimating the variance of these random effects across this population. Such an effect is also called a *random slope*.

When there are no theoretical or other prior guidelines about which variables should have a random effect, the researcher can be led by the substantive focus of the investigation, the empirical findings, and parsimony of modeling. This implies that those explanatory variables that are especially important or have especially strong effects could be modeled with random effects, if the variances of these effects are important enough as evidenced by their significance and size, but one should take care that

2 Fixed and Random Effects

the number of variables with random effects should not be so large that the model becomes unwieldy.

Modeling an effect as random usually – although not necessarily – goes with the assumption of a normal distribution for the random effects. Sometimes, this is not in accordance with reality, which then can lead to biased results. The alternative, entertaining models with nonnormally distributed residuals, can be complicated, but methods were developed, see [2]. In addition, the assumption is made that the random effects are uncorrelated with the explanatory variables. If there are doubts about normality or independence for a so-called nuisance effect, that is, an effect the researcher is interested in not for its own sake but only because it must be statistically controlled for, then there is an easy way out. If the doubts concern the main effect of a categorical variable, which also would be a candidate for being modeled as a level as discussed above, then the easy solution (at least for linear models) is to model this categorical control variable by fixed effects, that is, using **dummy variables** for the units in the sample. If it is a random slope for which such a statistical control is required without making the assumption of residuals being normally distributed and independent

of the other explanatory variables, then the analog is to use an interaction variable obtained by multiplying the explanatory variable in question by the dummy variables for the units. The consequence of this easy way out, however, is that the statistical generalizability to the population of these units is lost (see **Generalizability**).

Fixed Effect Models

Typically, a term associated with the application of **analysis of variance in experimental designs**, fixed-effect refers to a type of independent variable or factor. Most researchers employing experimental designs use fixed-effect models in that the levels of the independent variables are finite, known, and in most cases, manipulated by the researcher to be reasonably different to detect a difference on the dependent variable if there is any internal validity to the independent variable. Examples include gender (two-level factor), comparing the impact of the only three drugs known to address a specific condition (three-level factor), or creating different experimental conditions such as receiving negative performance feedback from a same race versus a different race confederate rating source (three-level factor). Fixed-effect independent variables differ from random factors in experimental designs. Random factors are independent variables that consist of a pool of potential levels, and thus, the levels are not manipulated by the researcher but rather sampled. For example, assume that a researcher is interested in examining the impact of a particular management practice on nurse retention in hospitals of a given state. The fixed factor would be the presence and absence of the management practice, but since it is highly improbable that the researcher can undertake this experiment in all hospitals, a random sample (usually conducted systematically such as employing stratified schemes) of hospitals would be selected. Hospitals would be the random factor.

A common criticism of purely fixed-effect designs, particularly those where the levels of the independent variable are the design of the researcher, is the fact that the results may only be generalized to comparable levels of that independent variable

within the population. In contrast, results from purely random factor models presumably are generalizable because the levels included in the experiment were randomly selected, and hence, will be representative of the population at large. As indicated in the hospital example above, if a random factor is included, it is typically crossed with a fixed-effect factor, which constitutes a mixed model design. While the technical explanation for the following is provided in the attached references, the inclusion of random factors complicates the analysis in that the error term for evaluating effects (main or interaction) is different. For example, assume we have two fixed-effect independent variables, A and B. The significance of their main and interaction effects are evaluated against the same source of error variance; the within-group mean square error. If A were a random factor, however, the main effect of B (the fixed factor) would need to be evaluated against a different source of error variance because the interaction effect intrudes upon the main effect of the fixed-effect factor. Not making the adjustment could result in detecting a main effect for B when none exists in reality.

Focus Group Techniques

Introduction

Given the training most scientists have received in quantitative techniques, focus group research is probably the most underrated of all research techniques. The term is inappropriately applied to activities ranging from broad discussions to town hall meetings. Some think of focus groups as the easiest technique to use; it does not require a tight questionnaire – just getting people to talk, and any person with reasonably good social skills can do that. Unlike that stereotype, however, focus groups require professional design, execution, and interpretation. Focus group research is an interview style designed for small groups. It can be seen as directed group brainstorming where a facilitator initiates a discussion and keeps it on topic as the responses of one participant serve as stimuli for other participants. Members' opinions about, or emotional response to, a particular topic, procedure, or product are used in market, political, and social science research.

Techniques

Several good handbooks on focus group techniques are available, for example, Greenbaum [2] and Client Guide to Focus Groups [1]. A brief overview of the focus group technique follows.

Because focus groups 'focus' on a specific concern and a specific category of participants, most focus group research is client driven. When contacted by the client, the researcher must determine whether focus group research is the best technique to use. Focus group research is a qualitative method by which the researcher gains in-depth, sensitive data. However, it is not a reliable technique for collecting quantitative information. It cannot produce frequencies or percentages because the participants are not necessarily representative – the number of participants is too small and they do not have the same proportions of subgroups as the population in question. Therefore, focus groups should not be used to uncover complex relationships that require sophisticated statistical techniques. Also, future projections based on focus groups are inferior to those based on the past experiences of large numbers of people.

If focus group research is the appropriate method, then the researcher must establish what the client wants to know and from whom the information can be gained – the targeted customers or clients. One of the most time consuming, and expensive, aspects of focus group research is locating and gaining the cooperation of members of the target population. Focus groups, because they are small, are rarely representative samples of a given population. The usual technique is to conduct focus groups until the responses of the targeted population are exhausted – continuing until responses are mostly repetitive. Sometimes this can be accomplished with two focus groups if the respondents are not divided by categories such as age, gender, level of income, and previous use of the product, and so on, in an effort to fine-tune responses. Respondents in each focus group should be similar to enhance the comfort level and the honesty of responses and thereby avoid attempts to protect the feelings of dissimilar others. For example, a study conducted by the authors on attitudes toward birth control among teenagers divided respondents by gender (2 categories), age (3 categories), ethnicity (3 categories), and level of sexual activity (3 categories). This gave 54 different categories with at least two focus groups conducted in each, for a minimum of 108 focus group discussions. By using this procedure, 13–14 year-old, nonsexually active, white males were not in the same group with 17–18 year-old, pregnant, black females.

Eight to ten participants in a focus group is about average, depending on the topic and the category of the respondents. In the study mentioned above, six teenagers worked better than the usual 8 to 10 participants because they all wanted to talk and had information to share. Usually, more than eight to ten in a group is undesirable. If the group is too large, the discussants will not have an opportunity to express their attitudes on all facets of the topic.

Besides the discussants, a facilitator is needed who knows how to make the participants feel comfortable enough to disclose the needed information. This person knows how to get reticent members to contribute and how to limit the participation of those who would monopolize the conversation. The facilitator keeps the discussion on topic without appearing to overly structure it. These tasks are difficult to accomplish without alienating some participants unless the facilitator is well trained. The techniques for achieving

2 Focus Group Techniques

good facilitation, verbal and otherwise, are discussed in published research.

The facilitator and discussants are only the most obvious members of focus group research. Someone, usually the primary researcher, must meet with clients to determine the focus of the topic and the sample. Then, someone must locate the sample, frequently using a sampling screen, and contact them with a prepared script that will encourage their participation. Depending on the topic, the client, and the respondents' involvement with the issue, the amount that discussants are paid to participate varies. Participants are usually paid \$25 to \$50 dollars each. Professionals can usually only be persuaded to participate by the offer of a noon meeting, a catered lunch, and the promise that they will be out by 1:15. For professionals, money is rarely an effective incentive to participate. The script inviting them to participate generally states that although the money offered will not completely reimburse them for their time, it will help pay for their gas. Some participants are willing to attend at 5:30 so they can drop by on their way home from work. Older or retired participants prefer meetings in late morning, at noon, or at three in the afternoon. Other participants can only attend at around 7:30 or 9:00 in the evening. Groups are scheduled according to such demographic characteristics as age, location and vocation.

The site for the meeting must be selected for ease of accessibility for the participants. Although our facilities have adequate parking and can be easily accessed from the interstate and from downtown, focus groups for some of our less affluent participants have been held in different parts of the city, sometimes in agency facilities with which they are familiar and comfortable. Focus group facilities in most research centers have a conference room that is wired for audio and video and a one-way mirror for unobtrusive viewing. Participants are informed if they are being taped and if anyone is behind the mirror. They are told that their contributions are so important that the researchers want to carefully record them. In addition, our center also employs two note takers who are in the room, but not at the table, with the discussants. They are introduced when the procedure and reasons for the research are explained, but before the discussion begins. Note takers have the interview questions on a single sheet and record responses on a notepad with answers following the number of each question. They are instructed to type

up their answers the day of the interviews while the discussion is fresh in their minds and before they take notes on another group.

When all focus groups have been conducted, the primary investigator must organize the data so that it can be easily understood, interpret the data in terms of the client's goals, and make recommendations.

Focus groups are fairly expensive if done correctly. The facilitator's fee and the discussants' payments alone can run almost \$1000 per focus group. This amount does not include the cost of locating and contacting the participants, the note takers' payment, the facilities rental, data analysis, and report preparation.

Uses of Focus Groups

Focus group research has become a sophisticated tool for researching a wide variety of topics. Focus groups are used for planning programs, uncovering background information prior to quantitative surveys, testing new program ideas, discovering what customers consider when making decisions, evaluating current programs, understanding an organization's image, assessing a product, and providing feedback to administrators. Frequently linked with other research techniques, it can precede the major data-gathering technique and be used for general exploration and questionnaire design. Researchers can learn what content is necessary to include in questionnaires that are administered to representative samples of the target populations.

The focus group technique is used for a variety of purposes. One of the most widespread uses of focus groups involves general exploration into unfamiliar territory or into the area of new product development. Also, habits and usage studies utilize the focus group technique in obtaining basic information from participants about their use of different products or services and for identifying new opportunities to fill the shifting needs in the market. The dynamic of the focus group allows information to flow easily and allows market researchers to find the deep motivations behind people's actions. Focus groups can lead to new ideas, products, services, themes, explanations, thoughts, images, and metaphors.

Focus groups are commonly used to provide information about or predict the effectiveness of advertising campaigns. For example, participants can be

shown promotional material, or even the sales presentation in a series of focus groups. Focus groups also provide an excellent way for researchers to listen as people deliberate a purchase. The flexibility of focus groups makes them an excellent technique for developing the best positioning for products. They also are used to determine consumer reactions to new packaging, consumer attitudes towards products, services, programs, and for public relations purposes.

The authors have used focus groups to learn how to recruit Campfire Girls leaders, to uncover attitudes toward a river-walk development, to determine the strengths and needed changes for a citywide library system, to discover how to involve university alumni in the alumni association, to determine which magazine supplement to include in the Sunday newspaper; to learn ways to get young single nonsubscribers who read the newspaper to subscribe to it; to determine what signs and slogans worked best for political candidates; to determine which arguments worked best in specific cases for trial lawyers; to decide changes needed in a university continuing education program, to establish the packages and pricing for a new telecommunications company, to

uncover non-homeowner's opinions toward different loan programs that might put them in their own home, to determine which student recruitment techniques work best for a local community college, to discover how the birthing facilities at a local hospital could be made more user friendly, and to uncover attitudes toward different agencies supported by the United Way and ways to encourage better utilization of their services.

Focus groups are flexible, useful, and widely used.

Free Response Data Scoring

Introduction

The use of computers in assessment affords the opportunity for use of complex, interactive item formats. The availability of multimedia stimuli along with free-text, touch-screen, and voice-activated response formats offers a means of creating assessments that more closely approximate the 'real world' criterion behaviors of interest. However, for this expansion of assessment to be practically useful, it is necessary for the computer both to deliver and score assessments.

This entry presents the state of the art for computerized scoring of complex item formats. It begins by describing the types of procedures currently in use. The entry will then discuss the strengths and weaknesses of differing approaches. The discussion will conclude with comments of the future of automated scoring.

The State of the Art

It is common for technical and logistical issues to limit the extent to which a proficiency of interest can directly be assessed. Real-world tasks are often modified or abstracted to make assessment feasible (e.g., multiple-choice items may assess recognition rather than recall). This type of compromise has also been invoked in order to simplify the task of creating computerized scoring procedures. For example, the complex problem of scoring a task in which the examinee was required to write a computer program could be simplified substantially if the examinee were required to identify and correct errors in an existing program. Two papers by researchers from the Educational Testing Service (ETS) report on efforts to use artificial intelligence procedures to score computer programs. Bennett et al. [2] describe a complex algorithm designed to score constructed-response items in a computer science test. Evaluation of the procedure showed that it was of limited utility. Braun, Bennett, Frye, and Soloway [5] describe a procedure for scoring a simplified alternative task in which the examinee corrected errors in a computer

program rather than producing the program. With this modification, the examinee's changes to the program could be matched to a key and the complexity of the scoring task was therefore greatly constrained.

A similar approach to computerized scoring of a writing task was reported by Davey, Goodwin, and Mettelholtz [8]. They developed a computer-delivered writing task in which the examinee identifies and corrects errors in an essay. The examinee identifies sections of the essay that they believe contain an error. Possible corrections are presented, the examinee selects one, and that choice is then compared to a scoring key. As with the task from the computer science test, constraining the task makes computerized scoring more straightforward; it is a simple matter of matching to a key.

The previous paragraphs describe procedures that allow for scoring by direct matching of an examinee response to a specified key. Another general class of scoring procedures is represented by the approaches to scoring new item formats developed by researchers at ETS. These include mathematical reasoning [4], hypothesis formulation [10], and quantitative representation tasks [3]. With these formats, computerized scoring is accomplished by transforming examinee-constructed responses before matching them to a key. With one of the mathematical reasoning items, the examinee is given a verbal description and asked to produce a mathematical expression that represents the answer (e.g., 'During one week in Trenton in January, it snowed for s days and was fair on the other days. What is the probability that a randomly selected day from that week was fair?' (p. 164)). There are a nearly limitless number of equivalent ways that the mathematical expression could be formulated. For example:

$$1 - \frac{s}{7}$$

or,

$$\frac{7-s}{7}.$$

The format takes advantage of computer software that can reduce any mathematical expression to a base form. This allows for direct matching to a key and, unlike the examples given previously, the match to the key is made possible by the computer and not by restriction of the task posed to the examinee or to the response format.

The scoring procedures described to this point have in common that they allow for directly matching

2 Free Response Data Scoring

the response(s) to a simple key. In some sense, this is true of all scoring procedures. However, as the complexity of the key increases, so does the complexity of the required computer algorithm. Essay scoring has been a kind of Holy Grail of computerized scoring. Researchers have devoted decades to advancing the state of the art for essay scoring. Page's efforts [14, 15] have been joined by those of numerous others [9]. All of these efforts share in common the basic approach that quantifiable aspects of the performance are used to predict expert ratings for a sample of essays. Although the analytic procedures may vary, the regression procedures used by Page provide a conceptual basis for understanding the general approach used by these varying procedures. Early efforts in this arena used relatively simple variables. When the score was to be interpreted as a general measure of writing proficiency, this was a reasonable approach. More recently, the level of sophistication has increased as serious efforts were made to evaluate the content as well as the stylistic features of the essay. One obvious approach to assessing content is to scan the essay for the presence of 'key words'; an essay about the battle of Gettysburg might reasonably be expected to make reference to 'Pickett's charge'. This approach is less likely to be useful when the same concept can be expressed in many different ways. To respond to this problem, Landauer and Dumais [11] developed a procedure in which the relationship between words is represented mathematically. To establish these relationships, large quantities of related text are analyzed. The inferred relationships make it possible to define any essay in terms of a point in n -dimensional space. The similarity between a selected essay and other previously rated essays can then be defined as a function of the distance between the two essays in n -dimensional space.

Essays are not the only context in which complex constructed responses have been successfully scored by computer. Long-term projects by the National Council of Architectural Registration Boards [17] and the National Board of Medical Examiners (NBME) [12] have resulted in computerized scoring procedures for simulations used in certification of architects and licensure of physicians, respectively. In the case of the architectural simulations, the examinee uses a computer interface to complete a design problem. When the design is completed, the computer scores it by applying a branching rule-based algorithm that maps the presence or absence of

different design components into corresponding score categories.

With the computer-based case simulations used in medical licensure assessment, examinees manage patients in a simulated patient-care environment. The examinee uses free-text entry to order diagnostic tests and treatments and results become available after the passage of simulated time. As the examinee advances the case through simulated time, the patient's condition changes based both on the examinee's actions and the underlying problem. Boolean logic is applied to the actions ordered by the examinee to produce scorable items. For example, an examinee may receive credit for an ordered treatment if (a) it occurs after the results of an appropriate diagnostic test were seen, (b) if no other equivalent treatment had already been ordered, and (c) if the treatment were ordered within a specified time frame. After the logical statements are applied to the performance record to convert behaviors into scorable actions, regression-based weights are applied to the items to calculate a score on the case. These weights are derived using expert ratings as the dependent measure in a regression equation.

Empirical Results

Most of the empirical research presented to support the usefulness of the various procedures focuses on the correspondence between scores produced by these systems and those produced by experts. In general, the relationship between automated scores and those of experts is at least as strong as that between the same criterion and those produced by a single expert rater [7, 11, 12, 15]. In the case of the hypothesis generation and mathematical expression item types, the procedures have been assessed in terms of the proportion of examinee responses that could be interpreted successfully by the computer.

Several authors have presented conceptual discussions of the validity issues that arise with the use of computerized scoring procedures [1, 6]. There has, however, been relatively little in the way of sophisticated psychometric evaluation of the scores produced with these procedures. One exception is the evaluative work done on the NBME's computer-based case simulations. A series of papers summarized by Margolis and Clauser [12] compare not only the correspondence between ratings and automated scores

but (a) compare the generalizability of the resulting scores (they are similar), (b) examine the extent to which the results vary as a function of the group of experts used as the basis for modeling the scores (this was at most a minor source of error), (c) examine the extent to which the underlying proficiencies assessed by ratings and scores are identical (correlations were essentially unity), and (d) compare the performance of rule-based and regression-based procedures (the regression-based procedures were superior in this application).

Conceptual Issues

It may be too early in the evolution of automated scoring procedures to establish a useful taxonomy, but some conceptual distinctions between procedures likely will prove helpful. One such distinction relates to whether the criterion on which the scores are based is explicit or implicit. In some circumstances, the scoring rules can be made explicit. When experts can define scorable levels of performance in terms of variables that can directly be quantified by the computer, these rules can be programmed directly. Both the mathematical formulation items and the architectural problems belong to this category. These approaches have the advantage that the rules can be explicitly examined and openly critiqued. Such examination facilitates refinement of the rules; it also has the potential to strengthen the argument supporting the validity of the resulting score interpretations.

By contrast, in some circumstances it is difficult to define performance levels in terms of quantifiable variables. As a result, many of the currently used procedures rely on implicit, or inferred, criteria. Examples of these include essentially all currently available approaches for scoring essays. These procedures require expert review and rating of a sample of examinee performances. Scores are then modeled on the basis of the implicit relationship between the observed set of ratings and the quantifiable variables from the performances. The most common procedure for deriving this implicit relationship is **multiple linear regression**; Page's early work on computerized scoring of essays and the scoring of computer-based case simulations both took this approach. One important characteristic of the implicit nature of this relationship is that the quantified characteristics may

not actually represent the characteristics that experts consider when rating a performance; they may instead act as proxies for those characteristics.

The use of proxies has both advantages and disadvantages. One advantage is that it may be difficult to identify or quantify the actual characteristics of interest. Consider the problem of defining and quantifying the characteristics that make one essay better than another. However, the use of proxy variables may have associated risks. If examinees know that the essay is being judged on the basis of the number of words, and so on, they may be able to manipulate the system to increase their scores without improving the quality of their essays. The use of implicit criteria opens the possibility of using proxy measures as the basis for scoring, but it does not require the use of such measures.

Another significant issue in the use of computer-delivered assessments that require complex automated scoring procedures is the potential for the scores to be influenced by construct-irrelevant variance. To the extent that computer delivery and/or scoring of assessments results in modifying the assessment task so that it fails to correspond to the criterion 'real world' behavior, the modifications may result in construct-irrelevant variance. Limitations of the scoring system may also induce construct-irrelevant variance. Consider the writing task described by Davey, Goodwin, and Mettelholtz [8]. To the extent that competent writers may not be careful and critical readers, the potential exists for scores that are interpreted as representing writing skills to be influenced by an examinee's editorial skills. Similarly, in the mathematical expressions tasks, Bennett and colleagues [4] describe a problem with scoring resulting from the fact that, if examinees include labels in their expression (e.g., 'days'), the scoring algorithm may not correctly interpret expressions that would be scored correctly by expert review.

A final important issue with computerized scoring procedures is that the computer scores with mechanical consistency. Even the most highly trained human raters will fall short of this standard. This level of consistency is certainly a strength for these procedures. However, to the extent that the automated algorithm introduces error into the scores, this error will also be propagated with mechanical consistency. This has important implications because it has the potential to replace random errors (which will tend

to average out across tasks or raters) with systematic errors.

The Future of Automated Scoring

It does not require uncommon prescience to predict that the use of automated scoring procedures for complex computer-delivered assessments will increase both in use and complexity. The improvements in recognition of handwriting and vocal speech will broaden the range of the assessment format. The availability of low-cost computers and the construction of secure computerized test-delivery networks has opened the potential for large and small-scale computerized testing administrations in high and low-stakes contexts.

The increasing use of computers in assessment and the concomitant increasing use of automated scoring procedures seems all but inevitable. This increase will be facilitated to the extent that two branches of research and development are successful. First, there is the need to make routine what is now state of the art. The level of expertise required to develop the more sophisticated of the procedures described in this article puts their use beyond the resources available to most test developers. Secondly, new procedures are needed that will support development of task-specific keys for automated scoring. Issues of technical expertise aside, the human resources currently required to develop the scoring algorithms for individual tasks is well in excess of that required for testing on the basis of multiple-choice items. To the extent that computers can replace humans in this activity, the applications will become much more widely applicable.

Finally, at present, there are a limited number of specific formats that are scorable by computer; this entry has referenced many of them. New and increasingly innovative formats and scoring procedures are sure to be developed within the coming years. Technologies such as artificial **neural networks** are promising [16]. Similarly, advances in cognitive science may provide a framework for developing new approaches [13].

Friedman's Test

The nonparametric Friedman [4] test expands the **sign (S) test** to k related samples. The null hypothesis is that the samples come from the same population, which is tested against the alternative that at least one of the samples comes from a different population. The data are arranged in k columns and n rows, where each row contains k related observations. It is frequently positioned as an alternative to the parametric repeated measures one-way analysis of variance. Note that the Agresti-Pendergast procedure [1] and the Neave and Worthington [6] Match Test are often more powerful competitors to the Friedman test.

Procedure

Rank the observations for each row from 1 to k . For each of the k columns, the ranks are added and averaged, and the mean is designated $\bar{R}_j$. The mean of the ranks is $\bar{R} = 1/2(k + 1)$. The sum of the squares of the deviations of mean of the ranks of the columns from the mean rank is computed. The test statistic is a multiple of this sum.

Assumptions

It is assumed that the rows are independent and there are no tied observations in a row. Because comparisons are made within rows, tied values may not pose a serious threat. Typically, average ranks are assigned to ties.

Test Statistic

The test statistic, M , is a multiple of S :

$$S = \sum_{j=1}^k (\bar{R}_j - \bar{R})^2$$

$$M = \frac{12n}{k(k+1)} S, \quad (1)$$

where n is the number of rows, and k is the number of columns. An alternate formula is:

$$M = \frac{12}{nk(k+1)} \sum_{j=1}^k R_j^2 - 3n(k+1), \quad (2)$$

where n is the number of rows, k is the number of columns, and R_j is the rank sum for the j th column, $j = 1, 2, 3, \dots, k$.

Large Sample Sizes

For large sample sizes, the critical values can be approximated by the Chi-square distribution with $k - 1$ degrees of freedom. Monte Carlo simulations conducted by Fahoome and Sawilowsky [3] and Fahoome [2] indicated that the large sample approximation requires a minimum sample size of 13 for $\alpha = 0.05$, and 23 for $\alpha = 0.01$. Hodges, Ramsey, and Shaffer [5] provided a competitive alternative in computing critical values.

Example

Friedman's test is calculated with Samples 1 to 5 in the table below in Table 1, $n_1 = n_2 = n_3 = n_4 = n_5 = 15$.

The rows are ranked, with average ranks assigned to tied ranks as in Table 2.

The column sums are: $R_1 = 48.5$, $R_2 = 47.0$, $R_3 = 33.0$, $R_4 = 52.5$, and $R_5 = 44.0$. The sum of the squared rank sums is 10 342.5. $M = (12/15 \times 5 \times 6)(10\,342.5) - 3 \times 15 \times 6 = 0.02667(10\,342.5) - 270 = 5.8$. The large sample approximation of the critical value is 9.488, chi-square with $5 - 1 = 4$ degrees of freedom, and $\alpha = 0.05$. Because $5.8 <$

Table 1 Sample data

Sample 1	Sample 2	Sample 3	Sample 4	Sample 5

Functional Data Analysis

What is Functional Data Analysis?

Functional data analysis, or FDA, is the modeling of data using functional parameters. By a functional parameter, we mean a function whose shape and complexity is not known in advance of the analysis, and therefore the modeling process must provide as much flexibility in the estimated function as the data require. By contrast, more classical parametric approaches to function estimation assume a fixed form for the function defined by a small number of parameters, and focus on estimating these parameters as the goal of the modeling process. As a consequence, while FDA certainly estimates parameters, the attention is on the entire function rather than on the values of these parameters.

Some of the oldest problems in psychology and education are functional in nature. Psychophysics aims to estimate a curve relating a physical measurement to a subjective or perceived counterpart (*see Psychophysical Scaling*), and learning theory in its earlier periods attempted to model the relationship between either gain or loss of performance over time.

Many functional problems involve data where we can see the function in the data, but where we need to smooth the data in order to study the relation more closely (*see Kernel Smoothing; Scatterplot Smoothers*). Figure 1 shows the relation between measurements of the heights of 10 girls and their ages. The data are taken from the Berkeley Growth Study [5]. But, it is really Figure 2 that we need: The acceleration in height, or its second derivative, where we can see the pubertal growth spurt more clearly and how it varies, and a number of additional features as well (*see Growth Curve Modeling*).

However, other types of data require functional models even though the data themselves would not usually be seen as functional. A familiar example comes from test theory, where we represent for each test item the relation between the probability of an examinee getting an item correct to a corresponding position on a latent ability continuum (*see Item Response Theory (IRT) Models for Polytomous Response Data*). An example of three item response functions from an analysis reported in [4] is shown in Figure 3.

Figure 1 The heights of 10 girls. The height measurements are indicated by the circles. The smooth lines are height functions estimated using monotone smoothing methods (Data taken from [5])

Figure 2 The height acceleration curves, that is, the second derivatives, of the curves shown in Figure 1. The pubertal growth spurt is the large positive peak followed by the large valley, and the midpoint of the spurt is the age at which the curve crosses zero. The heavy dashed line is the cross-sectional mean of these curves, and indicates the need for registration or alignment of the pubertal growth spurt (Reproduced from [2] with permission from Springer)

In what follows, we will, for simplicity, refer to the argument t of a function $x(t)$ as ‘time’, but, in fact, the argument t can be space, frequency, depression level, or virtually any continuum. Higher dimensional arguments are also possible; an image, for example, is a functional observation with values defined over a planar region.

Figure 3 Three item response functions showing the relation between the probability of getting an item correct on a mathematics test as a function of ability (Reproduced from [4]. How are Functions Constructed in Functional Data Analysis?

Functions of arbitrary shape and complexity are constructed using a set of K functional building blocks called *basis functions*. These basis functions are combined linearly by multiplying each basis function $\phi_k(t)$, $k = 1, \dots, K$ by a coefficient c_k and summing results. That is,

$$x(t) = \sum_{k=1}^K c_k \phi_k(t). \quad (1)$$

A familiar example is the polynomial, constructed by taking linear combinations of powers of t . When $x(t)$ is constructed with a *Fourier series*, the basis functions are one of a series of sine and cosine pairs, each pair being a function of an integer multiple of a base frequency. This is appropriate when the data are periodic.

Where an unconstrained function is to be estimated, the preferred basis functions tend to be the splines, constructed by joining polynomial segments together at a series of values of t called knots. Splines have pretty much replaced polynomials for functional work because of their much greater flexibility and computational convenience (*see Scatterplot Smoothers*).

No matter what the basis system, the flexibility of the resulting curve is determined by the number K of basis functions, and a typical analysis involves determining how large K must be in order to capture the required features of the function being estimated.

Smoothness, Derivatives, and Functional Data Analysis

FDA assumes that the function being estimated is smooth. In practice, this means that the function has one or more derivatives that are themselves smooth or at least continuous. Derivatives play many roles in the technology of FDA. The growth curve analysis had the study of the second derivative as its immediate goal.

Derivatives are also used to quantify smoothness. A frequently used method is to define the total curvature of a function by the integral of the square of its second or higher-order derivative. This measure is called a *roughness penalty*, and a functional parameter is estimated by explicitly controlling its roughness.

In many situations, we need to study rates of change directly, that is, the *dynamics* of a process distributed over time, space, or some other continuum. In these situations, it can be natural to develop differential equations, which are functional relationships between a function and one or more of its derivatives. For example, sinusoidal oscillation in a function $x(t)$ can be expressed by the equation $D^2x(t) = -\omega^2x(t)$, where the notation $D^2x(t)$ refers to the second derivative of x , and $2\pi/\omega^2$ is the period. The use of FDA techniques to estimate differential equations has many applications in fields such as chemical engineering and control theory, but should also prove important in the emerging study of the dynamic aspects of human behavior.

We often need to fit functions to data that have special constraints. A familiar example is the probability

density function $p(t)$ that we estimate to summarize the distribution of a sample of N values t_i (see **Catalogue of Probability Density Functions**). A density function must be positive and must integrate to one. It is reasonable to assume that growth curves such as those shown in Figure 1 are strictly increasing. Item response functions must take values within the unit interval $[0, 1]$. Constrained functions like these can often be elegantly expressed in terms of differential equations. For example, any strictly increasing curve $x(t)$ can be expressed in terms of the equation $D^2x(t) = w(x)Dx(t)$, where the alternative functional parameter $w(t)$ has no constraints whatever. Estimating $w(t)$ rather than $x(t)$ is both easier and assures monotonicity.

Phase Variation and Registration in FDA

A FDA can confront new problems not encountered in multivariate and other older types of statistical procedures. One of these is the presence of phase variation, illustrated in Figure 2. We see there that the pubertal growth spurt varies in both amplitude and timing from girl to girl. This is because each child has a physiological age that does not evolve at the same rate as chronological age. We call this variation in timing of curve features *phase variation*.

The problem with phase variation is illustrated in the heavy dashed mean curve in Figure 2. Because girls are at different stages of their maturation at any particular clock age, the cross-sectional mean is a terrible estimate of the average child's growth pattern. The mean acceleration displays a pubertal growth spurt that lasts longer than that for any single girl, and also has less *amplitude variation* as well.

Before we can conduct even the simplest analyses, such as computing means and standard deviations, we must remove phase variation. This is done by computing a nonlinear, but strictly increasing, transformation of clock time called a *time warping function*, such that when a child's curve values are plotted against transformed time, features such as the pubertal growth spurt are aligned. This procedure is often called *curve registration*, and can be an essential first step in an FDA.

What are Some Functional Data Analyses?

Nearly all the analyses that are used in multivariate statistics have their functional counterparts. For example, estimating functional descriptive statistics such as mean curve, a standard deviation curve, and a bivariate *correlation function* are usual first steps in an FDA, after, of course, registering the curves, if required.

Then many investigators will turn to a functional version of **principal components analysis** (PCA) to study the dominant modes of variation among a sample of curves. Here, the principal component vectors in multivariate PCA become principal functional components of variation. As in ordinary PCA, a central issue is determining how many of these components are required to adequately account for the functional variation in the data, and rotating principal components can be helpful here, too. A functional analogue of **canonical correlation** analysis may also be useful.

Multiple regression analysis or the **linear model** has a wide range of functional counterparts. A functional **analysis of variance** involves dependent variables that are curves. We could, for example, compute a functional version of the t Test to see if the acceleration curves in Figure 2 differ between boys and girls. In such tests, it can be useful to identify regions on the t -axis where there are significant differences, rather than being content just to show that differences exist. This is the functional analogue of the multiple comparison problem (see **Multiple Comparison Procedures**).

What happens when an independent variable in a regression analysis is itself a function? Such situations often arise in medicine and engineering, where a patient or some industrial process produces a measurable response over time to a time-varying input of some sort, such as drug dose or raw material, respectively. In some situations, the effect of varying the input has an immediate effect on the output, and, in other situations, we need to compute causal effects over earlier times as well. Functional independent variables introduce a fascinating number of new technical challenges, as it is absolutely essential to impose smoothness on the estimated functional regression coefficients.

Differential equations are, in effect, functional linear models where the output is a derivative, and among the inputs are the function's value and

perhaps also those of a certain number of lower-order derivatives. Differential equations, as well as other functional models, can be linear or nonlinear. An important part of FDA is the emergence of new methods for estimating differential equations from raw noisy discrete data.

Resources for Functional Data Analysis

The field is described in detail in [3], a revised and expanded edition of [1]. A series of case studies involving a variety of types of FDA are described in [2].

Along with these monographs are a set of functions in the high-level computer languages R, S-PLUS, and Matlab that are downloadable from the web site www.functionaldata.org. This software comes with a number of sets of sample data, including the growth data used in this article, along with various analyses using these functions.

Fuzzy Cluster Analysis

Cluster analysis is an exploratory method used to classify, or to ‘cluster’, objects under consideration (see **Cluster Analysis: Overview**). However, the crisp membership of objects in clusters, derived by classic cluster analysis, is not always satisfactory. Consider a simple example.

Let the weights of fish in a pond be measured. Assume that there are two generations of fish, one $\frac{1}{2}$ years old and another $1\frac{1}{2}$ years old. The **histogram** of the distribution of weights may look like Figure 1.

This picture clearly suggests that there are two clusters, one with center at y_1 and another with center at y_2 . The crisp cluster analysis will assign a fish with a weight of less than y_0 to the first cluster and a fish with a weight greater than y_0 to the second cluster. Intuitively, it is a good assignment for weights x_1 and

x_2 (assigned to the first cluster) and for weights x_5 , x_6 , and x_7 (assigned to the second cluster). But the correct crisp assignment of weights x_3 and x_4 is not so obvious, let alone the point y_0 , which is exactly in the middle of the clusters’ center.

Fuzzy cluster analysis suggests considering a *partial membership* of objects in clusters. Partial membership of object i in cluster k is a real number u_{ik} between 0 (no membership) and 1 (full membership). The crisp cluster analysis may be considered as a particular case of fuzzy cluster analysis, where the values allowed for u_{ik} are only 0 and 1 (no intermediate value is allowed). In our example, assignment to clusters depends only on weight w , and thus membership in cluster k is a function $u_k(w)$. Figure 2 shows membership functions for crisp clustering, and Figure 3 shows a desired shape of membership function for fuzzy clustering.

There are many types of fuzzy cluster analyses. One of the most important is *probabilistic fuzzy*

Figure 1 A Histogram of distribution of weight of fish in a pond

Figure 2 Membership functions for crisp clustering

2 Fuzzy Cluster Analysis

Figure 3 Membership functions for fuzzy clustering

clustering, which requires that for every object i its memberships in all clusters sum to 1, $\sum_k u_{ik} = 1$. In this case, values u_{ik} may be treated as probabilities for object i to belong to cluster k .

As in the case of crisp cluster analysis, the inputs for the fuzzy cluster analysis are the results of m measurements made on n objects, which can be represented:

$$\begin{pmatrix} x_1^1 & x_2^1 & \dots & x_n^1 \\ x_1^2 & x_2^2 & \dots & x_n^2 \\ \vdots & \vdots & \ddots & \vdots \\ x_1^m & x_2^m & \dots & x_n^m \end{pmatrix} \quad (1)$$

The situation differs significantly, depending on whether measurements are continuous or categorical. First, we consider continuous measurements, for which fuzzy K -means algorithm will be discussed in detail and other methods will be briefly characterized. Then we will discuss methods for analyzing categorical data which may be used for fuzzy clustering.

Fuzzy Clustering of Continuous Data: Fuzzy K-means Algorithm

When the result of every measurement is a real number, the columns of matrix (1) (which represent objects) may be considered as points in m -dimensional space. In crisp K -means clustering, the goal is to split objects into K clusters $c_1, \dots, c_K$ with centers $\mathbf{v}_1, \dots, \mathbf{v}_K$ such that

$$\sum_{k=1}^K \sum_{x_i \in c_k} d(\mathbf{x}_i, \mathbf{v}_k) \quad (2)$$

achieves its minimum (see **k-means Analysis**). This may be reformulated as the minimization of

$$\sum_{k=1}^K \sum_{i=1}^n u_{ik} d(\mathbf{x}_i, \mathbf{v}_k), \quad (3)$$

with constraints

$$\sum_{k=1}^K u_{ik} = 1 \quad (4)$$

for every $i = 1, \dots, n$. The allowed values for u_{ik} are 0 and 1; therefore, (4) means that for every i , only one value among $u_{i1}, \dots, u_{iK}$ is 1 and all others are 0. The distance $d(\mathbf{x}, \mathbf{y})$ may be chosen from a wide range of formulas, but for computational efficiency it is necessary to have a simple way to compute centers of clusters. The usual choice is the squared Euclidean distance, $d(\mathbf{x}, \mathbf{y}) = \sum_j (x^j - y^j)^2$, where the center of a cluster is its center of gravity. For the sake of simplicity, we restrict our consideration to the squared Euclidean distance.

Equation (3) suggests that fuzzy clustering may be obtained by relaxing the restriction ' u_{ik} is either 0 or 1'; rather, u_{ik} is allowed to take any value in the interval $[0,1]$ and is treated as the degree of membership of object i in cluster k . However, this is not as simple as it appears. One can show that the minimum of (3) with constraints (4) is still obtained when u_{ik} are 0s or 1s, despite the admissibility of intermediate values. In this problem, an additional parameter $f \geq 1$, called a *fuzzifier*, can be introduced in (3):

$$\sum_{k=1}^K \sum_{i=1}^n (u_{ik})^f d(\mathbf{x}_i, \mathbf{v}_k) \quad (5)$$

The fuzzifier has no effect in crisp K -means clustering (as $0^f = 0$ and $1^f = 1$), but it produces nontrivial minima of (5) with constraints (4).

Now the fuzzy clustering problem is a problem of finding the minimum of (5) under constraints (4). The fuzzy K -means algorithm searches for this minimum by alternating two steps: (a) optimizing membership degrees u_{ik} while cluster centers $\mathbf{v}_k$ are fixed; and (b) optimizing $\mathbf{v}_k$ while u_{ik} are fixed. The minimum of (5), with respect to u_{ik} , is

$$u_{ik} = \frac{1}{\sum_{k'=1}^K \left(\frac{d(\mathbf{x}_i, \mathbf{v}_k)}{d(\mathbf{x}_i, \mathbf{v}_{k'})} \right)^{\frac{1}{f-1}}}, \quad (6)$$

and the minimum of (5), with respect to $\mathbf{v}_k$, is

$$\mathbf{v}_k = \frac{\sum_{i=1}^n (u_{ik})^f \mathbf{x}_i}{\sum_{i=1}^n (u_{ik})^f}. \quad (7)$$

Equation (7) is a vector equation; it defines a center of gravity of masses $(u_{1k})^f, \dots, (u_{nk})^f$ placed at

points $\mathbf{x}_1, \dots, \mathbf{x}_n$. The right side of formula (6) is undefined if $d(\mathbf{x}_i, \mathbf{v}_{k_0})$ is 0 for some k_0 ; in this case, one lets $u_{ik_0} = 1$ and $u_{ik} = 0$ for all other k . The algorithm stops when changes in u_{ik} and $\mathbf{v}_k$ during the last step are below a predefined threshold.

The fuzziness of the cluster depends on fuzzifier f . If f is close to 1, the membership is close to a crisp one; if f tends to infinity, the fuzzy K -means algorithm tends to give equal membership in all clusters to all objects. Figures 4, 5, and 6 demonstrate membership functions for $f = 2, 3, 5$. The most common choice for the fuzzifier is $f = 2$.

This method gives nonzero membership in all clusters for any object that does not coincide with the center of one of the clusters. Some researchers, however, prefer to have a crisp membership for objects close to cluster centers and fuzzy membership for objects that are close to cluster boundaries. One possibility was suggested by Klawonn and Hoepfner [4]. Their central idea is to consider subexpression u^f as a special case of function $g(u)$. To be used in place of the fuzzifier, such functions must (a) be a

Figure 4 Membership functions for $f = 2$

Figure 5 Membership functions for $f = 3$

Figure 6 Membership functions for $f = 4$

Figure 7 Membership functions for fuzzifier $g(u) = \frac{1}{2}u^2 + \frac{1}{2}u$

monotonically increasing map of the interval $[0,1]$ into itself with $g(0) = 0$, $g(1) = 1$; (b) must have a continuous increasing derivative; and (c) must satisfy $g'(0) < g'(1)$. The standard fuzzifier $g(u) = u^f$ possesses these properties, but this approach gives other choices. Klawonn and Hoepfner proved that to obtain crisp membership for objects close to cluster centers, $g(u)$ must satisfy $g'(0) > 0$. One possibility for such functions is $g(u) = \alpha u^2 + (1 - \alpha)u$ with $0 < \alpha < 1$. The membership functions for the fish example with fuzzifier $g(u) = 1/2u^2 + 1/2u$ are shown in Figure 7.

Although theoretically $g(u)$ may be chosen from a wide range of functions, to obtain a good equivalent of (6), it must have a sufficiently simple analytical form.

Fuzzy Clustering of Continuous Data: Other Approaches

Probabilistic fuzzy clustering gives approximately equal membership degrees in all clusters for objects that are far from all clusters. Moreover, ‘bad’ objects move cluster centers from the position defined by ‘good’ members. Several methods have been suggested to resolve this problem.

Noise clustering introduces an additional, aptly designated the ‘noise cluster’. The distance from any object to the noise cluster is the same large number. In this way, objects near the border between two normal clusters still receive nonzero membership in these clusters, while objects that are far away from all normal clusters become members of the noise cluster, and have no membership in normal clusters.

Possibilistic clustering tries to handle the problem by dropping the constraints (4). To avoid a trivial minimum of (5) (all degrees of membership are 0s),

(5) is modified to

$$\sum_{k=1}^K \sum_{i=1}^n (u_{ik})^f d(\mathbf{x}_i, \mathbf{v}_k) + \sum_{k=1}^K \eta_k \sum_{i=1}^n (1 - u_{ik})^f \quad (8)$$

The global minimum of (8) does not give a satisfactory solution, but local minima near a result of a fuzzy K -means clustering algorithm solution produce a good clustering. Minimization of (8) works exactly as minimization of (5) in the fuzzy K -means algorithm – with one exception: formula (6) for updating membership degrees is replaced by

$$u_{ik} = \frac{1}{1 + \left(\frac{d(\mathbf{x}_i, \mathbf{v}_k)}{\eta_k} \right)^{\frac{1}{f-1}}} \quad (9)$$

This formula also explains the meaning of coefficients η_k : it is the distance from the center of cluster $\mathbf{v}_k$, at which the membership degree equals 0.5. This suggests that the way to calculate η_k from an existing clustering is:

$$\eta_k = \alpha \frac{\sum_{i=1}^n (u_{ik})^f d(\mathbf{x}_i, \mathbf{v}_k)}{\sum_{i=1}^n (u_{ik})^f} \quad (10)$$

Usually, a possibilistic clustering is performed in three steps. First, a fuzzy K -means clustering is performed. Second, coefficients η_k are calculated using (10). Third, (8) is minimized by alternately applying formulas (9) and (7).

A different approach to fuzzy clustering arises from the theory of mixed distributions [2, 8, 10]. When objects under classification may be considered realizations of random variables (or, more generally, of random vectors), and the observed distribution law can be represented as a finite mixture of simpler distribution laws, component distribution laws may be

considered as clusters; consequently membership in a cluster is the probability of belonging to a component distribution law (conditional on observations) (see **Finite Mixture Distributions; Model Based Cluster Analysis**). In the fish example, the observed distribution law can be represented as a mixture of two normal distributions, which leads to two clusters similar to those previously considered.

The applicability of this approach is restricted in that a representation as a finite mixture may or may not exist, or may be not unique, even when an obvious decomposition into clusters is present in the data. On the other hand, although there is no obvious extension of the fuzzy K -means algorithm to categorical data, the mixed distribution approach can be applied to categorical data.

Fuzzy Clustering of Categorical Data: Latent Class Models

Latent structure analysis [3, 6, 7] deals with categorical measurements. The columns of (1) are vectors of measurements made on an object. These vectors may be considered as realizations of a random vector $\mathbf{x} = (X^1, \dots, X^m)$. We say that the distribution law of random vector $\mathbf{x}$ is independent, if component random variables $X^1, \dots, X^m$ are mutually independent.

The observed distribution law is not required to be independent; however, under some circumstances, it may be represented as a mixture of independent distribution laws. This allows considering a population as a disjointed union of classes ('latent' classes), such that the distribution law of random vector $\mathbf{x}$ in every class is independent. Probabilities for objects belonging to a class that is conditional on the outcomes of measurements can be calculated and can be considered as degrees of membership in corresponding classes (see **Latent Class Analysis**). Most widely used algorithms for construction of latent class models are based on maximizing the likelihood function and involve heavy computation.

Fuzzy Clustering of Categorical Data: Grade of Membership Analysis

Grade of membership (GoM) analysis [5, 9, 11] works with the same data as latent structure analysis. It also searches for a representation of the observed distribution as a mixture of independent distributions.

However, in GoM, though the mixture sought is allowed to be infinite, all mixed distributions must belong to a low-dimensional linear subspace Q of a space of independent distributions. Under weak conditions this linear subspace is identifiable, and the algorithm for finding this subspace reduces the problem to an **eigenvalue/eigenvector** problem.

The mixing distribution may be considered a distribution of a random vector $\mathbf{g}$ taking values in Q . Individual scores $\mathbf{g}_i$ are expectations of random vector $\mathbf{g}$ conditional on outcome of measurements $x_i^1, \dots, x_i^m$. Conditional expectations may be found as a solution of a linear system of equations. Let subspace Q be K -dimensional, $\lambda^1, \dots, \lambda^K$ be its basis, and let $g_i^1, \dots, g_i^K$ be coordinates of the vector of individual scores $\mathbf{g}_i$ in this basis. Often, for an appropriate choice of basis, g_i^k may be interpreted as a partial membership of object i in cluster k . Alternatively, a crisp or fuzzy clustering algorithm may be applied to individual scores $\mathbf{g}_i$ to obtain other classifications. The low computational complexity of the GoM algorithm makes it very attractive for analyzing data involving a large number (hundreds or thousands) of categorical variables.

Example: Analysis of Gene Expression Data

We used as our example gene expression data – the basis of Figure 2 in [1]. These authors performed a hierarchical cluster analysis on 2427 genes in the yeast *S. cerevisia*. Data were drawn at time points during several processes given in Table 1, taken from footnotes in [1]: for example, cell division after synchronization by alpha factor arrest (ALPH; 18 time points) after centrifugal elutriation (ELU; 14 time points).

Gene expression (log ratios) was measured for each of these time points and subjected to hierarchical cluster analysis. For details of their cluster analysis method, see [1]. They took the results of their cluster analysis and made plots of genes falling in various clusters. Their plots consisted of raw data values (log ratios) to which they assigned a color varying from saturated green at the small end of the scale to saturated red at the high end of the scale. The resulting plots exhibited large areas similarly colored. These areas indicated genes that clustered together.

6 Fuzzy Cluster Analysis

Table 1 Cell division processes

Process type	Time points	Process description
ALPH	18	Synchronization by alpha factor arrest
ELU	14	Centrifugal elutriation
CDC15	15	Temperature-sensitive mutant
SPO	11	Sporulation
HT	6	High-temperature shock
Dtt	4	Reducing agents
DT	4	Low temperature
DX	7	Diauxic shift

The primary purpose of this example is to describe the use of GoM for fuzzy cluster analysis. A secondary purpose was to identify some genes that cluster together and constitute an interesting set. To use the Grade of Membership (GoM) model, we categorized the data by breaking each range of expression into 5 parts – roughly according to the empirical distribution. GoM constructs K groups (types) types with different characteristics to explain heterogeneity of the data. The product form of the multinomial GoM likelihood for categorical variables x_{ij} is:

$$L = \prod_L \prod_j \prod_\ell (p_{ij\ell})^{y_{ij\ell}}, \quad (11)$$

where

$$p_{ij\ell} = \sum_{h=1}^K g_{ih} \lambda_{hj\ell} \quad (12)$$

with constraints $g_{ih}, \lambda_{hj\ell} \geq 0$ for all i, h, j, ℓ and $\sum_{h=1}^K g_{ih} = 1$ for all i ; $\sum_{\ell=1}^{L_j} \lambda_{hj\ell} = 1$ for all h, j . $y_{ij\ell}$ is the binary coding of x_{ij} .

In (11), $p_{ij\ell}$ is the probability that observation i gives rise to the response that ℓ for variable j ; $\lambda_{hj\ell}$ is the probability that an observation belonging exclusively to type h gives rise to the response ℓ for variable j ; g_{ih} is the degree to which observation i belongs to type h ; L_j is the number of possible values for variable j ; and K is the number of types needed to fully characterize the data and must be specified. The parameters $\{g_{ih}, \lambda_{hj\ell}\}$ are estimated from (11) by the principle of maximum likelihood.

In practice, one starts with a low value of $K = K_0$, usually 4 or 5. Then, analogous to the way one fits a polynomial, successively higher values of K are tried until increasing K does not improve the fit. One of the important features of GoM is that, by inspecting

the whole ensemble of $\lambda_{hj\ell}$ for one value of K , one can construct a description of each type that usually ‘makes sense’. For most of the analyses done with GoM, K works out to be between 5 and 7. For this analysis runs for K as high as 15 were done before settling on $K = 10$ for this analysis. The program DSIGoM available from dsisoft.com was used for the computations. Further analysis was done by standard statistical programs.

The sizes of the types are 205.8, 364.1, 188.7, 234.1, 386.1, 202.4, 211.2, 180.0, 187.9, and 207.2 for types 1 through 10 respectively. Although the GoM analysis makes a partial assignment of each observation or case to the 10 types, it is sometimes desirable to have crisp assignment. A forced crisp assignment can be made by assigning the case to the type k^* with the largest membership. For the i th case, define k_i^* such that $g_{ik}^* > g_{ih}$ for all $h \neq k^*$.

The GoM output consists of the profiles (or variable clusters) characterized by the $\{\lambda_{hj\ell}\}$ and the grades of membership $\{g_{ih}\}$ values along with several goodness-of-fit measures. To construct clusters from the results of the GoM analysis, one can compare the Empirical Cumulative Distribution Function (CDF) for each type with the CDF for the population frequencies. This is done for each variable in the analysis. Based on the CDFs for each variable, a determination was made whether the type upregulated or downregulated gene expression more than the population average. Results of this process are given in Table 2.

‘D’ means that the type downregulates gene expression *for that variable* more than the population. A value of ‘U’ indicates the type upregulates gene expression for the variable more than the population average. A ‘blank’ value indicates that gene regulation for the type did not differ from the population average. In Table 2, Type 4 downregulates ALPH stress test expression values for all experiment times while Type 8 upregulates the same expression values for all experiment times. Types 4 and 8 represent different dimensions of the sample space. Heterogeneity of the data is assumed to be fully described by the 10 types. Descriptions for all 10 types are given in Table 3.

The g_{ih} represent the degree to which the i th case belongs to the h th type or cluster. Each case was assigned the type with the largest g_{ih} value. The 79 data values for each case were assigned colors according to the scheme used by [1] and plotted. We

include the plots for Type 4 and Type 8. These plots are designated Figures 8 and 9 respectively. Since the figures are illustrative, not substantive, actual gene names are not indicated. Inspection of Figure 8 shows large areas of green for the ALPH stress tests and for the earlier Elu tests, indicating clusters of downregulated genes. There are large areas of green for heat and cold tests, indicating downregulation. One can also see smaller clusters of reddish areas, indicating upregulated genes connected to later time points for Elu tests. In Figure 9 for Type 8, there is a significant clustering of pink and red areas for ALPH indicating a group of upregulated genes. The same genes are downregulated for the early test times of Elu and CDC 15, indicated by splotches of green.

The clusters designated Type 4 and Type 8 are not the same size. In a GoM model, the sizes of the types are computed by summing all g_{ih} values over i giving 205.0 for Type 4 and 180.0 for Type 8.

Table 3 Summary type descriptions

Type 1	Downregulates early ALPH time points, late CDC_15, Spo, heat, dtt, cold, diauxic. Upregulates Elu.
Type 2	Gene expression for ALPH does not deviate substantially from the population. * Downregulates Elu; does not convincingly regulate other processes.
Type 3	Downregulates Elu, CDC_15, dtt, early diauxic. Upregulates mid-range Spo, heat, cold.
Type 4	Downregulates ALPH, early Elu, heat cold, early diauxic. For CDC_15, it appears to downregulate in the mid-range but upregulate in the extremes.
Type 5	With spotty indication of both upregulation and downregulation; it most resembles the population.
Type 6	Strongly upregulates Spo.
Type 7	Upregulates early ALPH, early and late Elu, early and late CDC. Downregulates Spo. Upregulates heat, dtt, cold, diauxic.
Type 8	Upregulates ALPH, some indication for Elu, CDC_15, Spo, and early diauxic.
Type 9	Upregulates CDC_15, dtt, Spo mid and early, diauxic.
Type 10	Upregulates mid and late ALPH, Elu, possibly early CDC_15, early dtt, early diauxic. Downregulates early and mid Spo, heat, late dtt, cold, late diauxic.

Figure 9 Gene expression patterns for Type 8

Summary

Hierarchical clustering methods require choosing a distance function value to determine how many leaf level clusters will be in the analysis. There is no available statistical test to determine how many clusters are required (*see Number of Clusters*). Grade of Membership Analysis determines the number of clusters required by standard statistical tests with known properties. Because individual variability in the data

is represented in GoM by partial cluster memberships, the number of clusters required to adequately describe the data is less than for other methods. Coupled with the fact that GoM does not require specific distributional assumptions, Grade of Membership Analysis would be usually be preferred on parsimonious and theoretical grounds. GoM simultaneously clusters both variables and cases (a property it shares with latent class analysis). The λ_{hjl} define variable clusters and g_{ih} define clusters of cases. The g_{ih} define the degree to which each case belongs to each of the clusters.

Galton, Francis

Born: February 16, 1822, in Birmingham, UK.

Died: January 17, 1911, in Surrey, UK.

Sir Francis Galton (knighted in 1909) and Charles Darwin were grandsons of Erasmus Darwin, Darwin by first wife, Mary, and Galton by second wife, Elizabeth [3]. After an unsuccessful stint in the medical school of Kings College, London, Galton enrolled at Trinity College, Cambridge, and studied mathematics. Instead of working for honors, a ‘breakdown’ that he attributed to ‘overwork’ justified taking a ‘poll degree’ [4]. Nevertheless, Galton’s intellect (estimated IQ of 200; see [6]) and inherited financial independence enabled him to become so accomplished that in his obituary in *Nature* he was ranked among such leading nineteenth-century British scientists as Darwin, Kelvin, Huxley, and Clerk-Maxwell [1].

Galton had more than 300 publications including 17 books (see [4, Appendix III]) with *Hereditary Genius* [5] being one of the most important. He later regretted using the term ‘genius’, preferring instead a statistically defined ‘eminence’. His honors, interests, and inventiveness ranged widely. He received a gold medal and fellowship in the Royal Society for his geographical explorations in Africa. Fundamental contributions in meteorology included weather mapping and establishing the existence of *anti-cyclones*, a term he coined. He constructed methods for physical and psychological measurement, including composite photography of faces, in anthropology. He developed ways to identify and compare fingerprints as used in identification/investigation today. He did pioneering studies of mental measurement in psychology. He studied the efficacy of prayer, and introspected his self-induced worship of idols and self-induced paranoia. His inventions included a supersonic whistle, diving spectacles, and a periscope for peering over crowds.

In genetics, although he erred in adopting Darwin’s views of genetic blending, Galton anticipated Mendel’s work on particulate inheritance, including the distinction between **genotype** and phenotype (which Galton termed *latent* and *patent*). He was the first to use twins in investigations of morphological and behavioral genetics. He coined the term *eugenic*, and most of his work in genetics was done to support

programs to foster human eugenics. Although much tainted today, eugenics was widely popular in Great Britain, the United States, and elsewhere during Galton’s time, and, of course, it persists in milder forms today (standardized testing for university admissions, scholarships, etc.).

Galton’s contributions to statistical theory and methods were primarily in conjunction with genetics and psychology. He reversed the usual applications of the Gaussian Law of Errors to reduce variability and, instead, emphasized the importance of variability itself, which led to new directions for biological and psychological research [6]. In 1877, Galton published a numerical measure of ‘reversion’ or ‘regression’ to express relationships between certain parent–child physical characteristics. Plotting such data graphically led to his publication (1885) of the ‘elliptic contour’ (see graph in [5, p. 191]) and that led directly to his 1888 paper, ‘Co-relations and their measurement, chiefly from anthropometric data’ (see [5]). This paper provided the first means to calculate a coefficient of correlation.

Galton used the ‘*r*’ from his earlier work on ‘regression’ to symbolize the correlation coefficient, and he introduced the familiar way of expressing such coefficients as decimal fractions ranging from -1.0 to $+1.0$. However, he used the interquartile distance as his measure of variation, which would be replaced by the standard deviation in Karl **Pearson’s product-moment correlation coefficient**.

Galton’s legacy in genetics and statistics was carried forward by his friend Karl Pearson in the following ways: first, they combined Galton’s Eugenics Record Office with Pearson’s Biometric Laboratory to establish the Galton Laboratory at University College, London. Galton then provided funds to establish the journal *Biometrika*, and by his will following his death, he funded the Galton National Chair in Eugenics. He expressed his wish, which was honored, that Pearson be the first such professor [2]. As holder of the Galton chair, Pearson formed a department of genetics and statistics, a legacy that remains today as two separate departments in University College, London [7].

Game Theory

Background

Game theory is a formal theory of interactive decision making, used to model any decision involving two or more decision makers, called *players*, each with two or more ways of acting, called *strategies*, and well-defined preferences among the possible outcomes, represented by numerical *payoffs*.

In the theory, a player can represent an individual human decision maker or a corporate decision-making body, such as a committee or a board. A (pure) strategy is a complete plan of action, specifying in advance what *moves* a player would make – what actions the player would perform – in every contingency that might arise. If each player has only one decision to make and the players decide simultaneously, then the concept of a strategy coincides with that of a move, but in more complicated cases, a strategy is a comprehensive plan specifying moves in advance, taking account of all possible counter-moves of the coplayer(s). A *mixed strategy* is a probability distribution over a player's set of pure strategies. It is usually interpreted as a strategy chosen at random, with a fixed probability assigned to each pure strategy, as when a player tosses a coin to choose between two pure strategies with equal probabilities. In Bayesian interpretations of game theory, initiated by Harsanyi [12], a mixed strategy is sometimes interpreted as a coplayer's uncertainty about a strategy choice. Payoffs represent players' von Neumann–Morgenstern utilities, which are (roughly) their true preferences on an interval scale of measurement, as revealed by the assumedly consistent choices that they make in lotteries in which the outcomes have known probabilities assigned to them. A player's *payoff function* is a mapping that assigns a specific payoff to each outcome of the game.

The conceptual groundwork of game theory was laid by Zermelo, Borel, von Neumann, and others in the 1920s and 1930s (*see* [10]), and the first fully developed version of the theory appeared in *Theory of Games and Economic Behavior* by von Neumann and Morgenstern [31]. The theory began to have a significant impact on the behavioral and social sciences after the publication in 1957 of a more accessible text entitled *Games and Decisions* by Luce and Raiffa [18]. The early game theorists considered

the chief goal of the theory to be that of prescribing what strategies rational players *ought* to choose to maximize their payoffs. In this sense, the theory, in its classical form, is primarily *normative* rather than *positive* or *descriptive*. An additional rationality assumption, that people generally try to do the best for themselves in any given circumstances, makes the theory relevant to the empirical behavioral sciences and justifies experimental games (*see* section titled Experimental Games below); and in evolutionary game theory, the rationality assumption is replaced by replicator dynamics or adaptive learning mechanisms (*see* section titled Evolutionary Game Theory).

Basic Assumptions

In conventional decision theory, rational choice is defined in terms of maximizing expected utility (EU), or subjective expected utility (SEU), where the objective probabilities of outcomes are unknown (*see* utility theory). But this approach is problematic in games because each player has only partial control over the outcomes, and it is generally unclear how a player should choose in order to maximize EU or SEU without knowing how the other player(s) will act. Game theory, therefore, incorporates not only rationality assumptions in the form of expected utility theory, but also common knowledge assumptions, enabling players to anticipate one another's strategies to some extent, at least. The standard common knowledge and rationality (CKR) assumptions are as follows:

CKR1 (common knowledge): The specification of the game, including the players' strategy sets and payoff functions, is *common knowledge* in the game, together with everything that can be deduced logically from it and from the rationality assumption CKR2.

CKR2 (rationality): The players are rational in the sense of expected utility theory – they always choose strategies that maximize their individual expected payoffs, relative to their knowledge and beliefs – and this is *common knowledge* in the game.

The concept of *common knowledge* was introduced by Lewis [16] and formalized by Aumann [1]. A proposition is common knowledge if every player knows it to be true, knows that every other player knows it to be true, knows that every other player knows that every other player knows it to be true, and

so on. This is an everyday phenomenon that occurs, for example, whenever a public announcement is made, so that everyone present not only knows it, but knows that others know it, and so on [21].

Key Concepts

Other key concepts of game theory are most easily explained by reference to a specific example. Figure 1 depicts the best known of all strategic games, the *Prisoner's Dilemma game*. The figure shows its *payoff matrix*, which specifies the game in *normal form* (or *strategic form*), the principal alternative being *extensive form*, which will be illustrated in the section titled Subgame-perfect and Trembling-hand Equilibria. Player I chooses between the rows labeled *C* (cooperate) and *D* (defect), Player II chooses between the columns labeled *C* and *D*, and the pair of numbers in each cell represent the payoffs to Player I and Player II, in that order by convention. In *noncooperative game theory*, which is being outlined here, it is assumed that the players choose their strategies simultaneously, or at least independently, without knowing what the coplayer has chosen. A separate branch of game theory, called *cooperative game theory*, deals with games in which players are free to share the payoffs by negotiating coalitions based on binding and enforceable agreements. The rank order of the payoffs, rather than their absolute values, determines the strategic structure of a game. Replacing the payoffs 5, 3, 1, 0 in Figure 1 by 4, 3, 2, 1, respectively, or by 10, 1, -2, -20, respectively, changes some properties of the game but leaves its strategic structure (Prisoner's Dilemma) intact.

The Prisoner's Dilemma game is named after an interpretation suggested in 1950 by Tucker [30] and popularized by Luce and Raiffa [18, pp. 94–97]. Two people, charged with joint involvement in a crime, are held separately by the police, who have insufficient evidence for a conviction unless at least one of them discloses incriminating evidence. The

police offer each prisoner the following deal. If neither discloses incriminating evidence, then both will go free; if both disclose incriminating evidence, then both will receive moderate sentences; and if one discloses incriminating evidence and the other conceals it, then the former will be set free with a reward for helping the police, and the latter will receive a heavy sentence. Each prisoner, therefore, faces a choice between cooperating with the coplayer (concealing the evidence) and defecting (disclosing it). If both cooperate, then the payoffs are good for both (3, 3); if both defect, then the payoffs are worse for both (1, 1); and if one defects while the other cooperates, then the one who defects receives the best possible payoff and the cooperator the worst, with payoffs (5, 0) or (0, 5), depending on who defects.

This interpretation rests on the assumption that the utility numbers shown in the payoff matrix do, in fact, reflect the prisoners' preferences. Considerations of loyalty and a reluctance to betray a partner-in-crime might reduce the appeal of being the sole defector for some criminals, in which case that outcome might not yield the highest payoff. But the payoff numbers represent von Neumann–Morgenstern utilities, and they are, therefore, assumed to reflect the players' preferences after taking into account such feelings and everything else affecting their preferences. Many everyday interactive decisions involving cooperation and competition, trust and suspicion, altruism and spite, threats, promises, and commitments turn out, on analysis, to have the strategic structure of the Prisoner's Dilemma game [7]. An obvious example is price competition between two companies, each seeking to increase its market share by undercutting the other.

How should a rational player act in a Prisoner's Dilemma game played once? The first point to notice is that *D* is a *best reply* to both of the coplayer's strategies. A best reply (or best response) to a coplayer's strategy is a strategy that yields the highest payoff against that particular strategy. It is clear that *D* is a best reply to *C* because it yields a payoff of 5, whereas a *C* reply to *C* yields only 3; and *D* is also a best reply to *D* because it yields 1 rather than 0. In this game, *D* is a best reply to both of the coplayer's strategies, which means that defection is a best reply whatever the coplayer chooses. In technical terminology, *D* is a *dominant strategy* for both players. A dominant strategy is one that is a best

		II	
		C	D
I	C	3,3	0,5
	D	5,0	1,1

Figure 1 Prisoner's Dilemma game

reply to *all* the strategies available to the coplayer (or coplayers, if there are several).

Strategic dominance is a decisive argument for defecting in the one-shot Prisoner's Dilemma game – it is in the rational self-interest of each player to defect, whatever the other player might do. In general, if a game has a dominant strategy, then a rational player will certainly choose it. A dominated strategy, such as *C* in the Prisoner's Dilemma game, is *inadmissible*, inasmuch as no rational player would choose it. But the Prisoner's Dilemma game embodies a genuine paradox, because if both players cooperate, then each receives a better payoff (each gets 3) than if both defect (each gets 1).

Nash Equilibrium

The most important “solution concept” of game theory flows directly from best replies. A *Nash equilibrium* (or *equilibrium point* or simply *equilibrium*) is an outcome in which the players' strategies are best replies to each other. In the Prisoner's Dilemma game, joint defection is a Nash equilibrium, because *D* is a best reply to *D* for both players, and it is a unique equilibrium, because no other outcome has this property. A Nash equilibrium has strategic stability, because neither player could obtain a better payoff by choosing differently, given the coplayer's choice, and the players, therefore, have no reason to regret their own choices when the outcome is revealed.

The fundamental theoretical importance of Nash equilibrium rests on the fact that if a game has a uniquely rational solution, then it must be a Nash equilibrium. Von Neumann and Morgenstern [31, pp. 146–148] established this important result via a celebrated *indirect argument*, the most frequently cited version of which was presented later by Luce and Raiffa [18, pp. 63–65]. Informally, by CKR2, the players are expected utility maximizers, and by CKR1, any rational deduction about the game is common knowledge. Taken together, these premises imply that, in a two-person game, if it is uniquely rational for the players to choose particular strategies, then those strategies must be best replies to each other. Each player can anticipate the coplayer's rationally chosen strategy (by CKR1) and necessarily chooses a best reply to it (by CKR2); and because the strategies are best replies to each other, they are in

Nash equilibrium by definition. A uniquely rational solution must, therefore, be a Nash equilibrium.

The indirect argument also provides a proof that a player cannot solve a game with the techniques of standard (individual) decision theory (*see* strategies of decision making) by assigning subjective probabilities to the coplayer's strategies as if they were states of nature and then simply maximizing SEU. The proof is by *reductio ad absurdum*. Suppose that a player were to assign subjective probabilities and maximize SEU in the Prisoner's Dilemma game. The specific probabilities are immaterial, so let us suppose that Player I, for whatever reason, believed that Player II was equally likely to choose *C* or *D*. Then, Player I could compute the SEU of choosing *C* as $1/2(3) + 1/2(0) = 1.5$, and the SEU of choosing *D* as $1/2(5) + 1/2(1) = 3$; therefore, to maximize SEU, Player I would choose *D*. But if that were a rational conclusion, then by CKR1, Player II would anticipate it, and by CKR2, would choose (with certainty) a best reply to *D*, namely *D*. This leads immediately to a contradiction, because it proves that Player II was not equally likely to choose *C* or *D*, as assumed from the outset. The only belief about Player II's choice that escapes contradiction is that Player II will choose *D* with certainty, because joint defection is the game's unique Nash equilibrium.

Nash proved in 1950 [22] that every game with a finite number of pure strategies has at least one equilibrium point, provided that the rules of the game allow mixed strategies to be used. The problem with Nash equilibrium as a solution concept is that many games have multiple equilibria that are nonequivalent and noninterchangeable, and this means that game theory is systematically indeterminate. This is illustrated in Figure 2, which shows the payoff matrix of the *Stag Hunt game*, first outlined in 1755 by Rousseau [26, Part II, paragraph 9], introduced into the literature of game theory by Lewis [16, p. 7], brought to prominence by Aumann [1], and discussed

		II	
		<i>C</i>	<i>D</i>
I	<i>C</i>	9,9	0,8
	<i>D</i>	8,0	7,7

Figure 2 Stag Hunt game

in an influential book by Harsanyi and Selten [13, pp. 357–359]. It is named after Rousseau’s interpretation of it in terms of a hunt in which joint cooperation is required to catch a stag, but each hunter is tempted to go after a hare, which can be caught without the other’s help. If both players defect in this way, then each is slightly less likely to succeed in catching a hare, because they may end up chasing the same one.

This game has no dominant strategies, and the (C, C) and (D, D) outcomes are both Nash equilibria because, for both players, C is the best reply to C , and D is the best reply to D . In fact, there is a third Nash equilibrium – virtually all games have odd numbers of equilibria – in which both players use the mixed strategy $(7/8C, 1/8D)$, yielding expected payoffs of $63/8$ to each. The existence of multiple Nash equilibria means that formal game theory specifies no rational way of playing this game, and other psychological factors are, therefore, likely to affect strategy choices.

Payoff Dominance

Inspired by the Stag Hunt game, and in an explicit attempt to provide a method for choosing among multiple equilibria, Harsanyi and Selten’s *General Theory of Equilibrium Selection in Games* [13] introduced as axioms two auxiliary principles. The first and most important is the *payoff-dominance* principle, not to be confused with strategic dominance, discussed in the section titled Key Concepts. If e and f are two equilibria in a game, then e payoff-dominates (or Pareto-dominates) f if, and only if, e yields a strictly greater payoff to every player than f does. The payoff-dominance principle is the proposition that if one equilibrium payoff-dominates all others in a game, then the players will play their parts in it by choosing its strategies. Harsanyi and Selten suggested that this principle should be regarded as part of every player’s ‘concept of rationality’ and should be common knowledge among the players.

In the Stag Hunt game, (C, C) payoff-dominates (D, D) , and it also payoff-dominates the mixed-strategy equilibrium in which both players choose $(7/8C, 1/8D)$; therefore, the payoff-dominance principle requires both players to choose C . But this assumption requires collective reasoning that goes beyond the orthodox rationality assumption of CKR2.

Furthermore, it is not intuitively obvious that players should choose C , because, by so doing, they risk the worst possible payoff of zero. The D strategy is a far safer choice, risking a worst possible payoff of 7. This leads naturally to Harsanyi and Selten’s secondary criterion of selection among multiple equilibria, called the *risk-dominance* principle, to be used only if payoff dominance fails to yield a determinate solution. If e and f are any two equilibria in a game, then e risk-dominates f if, and only if, the minimum possible payoff resulting from the choice of e is strictly greater than the minimum possible payoff resulting from the choice of f , and players who follow the risk-dominance principle choose its strategies. In the Stag Hunt game, D risk-dominates C for each player, but the payoff-dominance principle takes precedence, because, in this game, it yields a determinate solution.

Subgame-perfect and Trembling-hand Equilibria

Numerous refinements of the Nash equilibrium concept have been suggested to deal with the problem of multiple Nash equilibria and the consequent indeterminacy of game theory. The most influential of these is the *subgame-perfect equilibrium*, introduced by Selten [27]. Selten was the first to notice that some Nash equilibria involve strategy choices that are clearly irrational when examined from a particular point of view. A simple example is shown in Figure 3.

The payoff matrix in Figure 3(a) specifies a game in which both (C, C) and (D, D) are Nash equilibria, but only (C, C) is subgame perfect. The Nash equilibrium (D, D) is not only weak (because 3 is not *strictly* greater than 3 for Player II) but also imperfect, because it involves an irrational choice from

Figure 3 Subgame-perfect equilibrium

Player II. This emerges most clearly from an examination of the *extensive form* of the game, shown in Figure 3(b). The extensive form is a *game tree* depicting the players' moves as if they occurred sequentially. This extensive form is read from Player I's move on the left. If the game were played sequentially, and if the second decision node were reached, then a utility-maximizing Player II would choose *C* at that point, to secure a payoff of 2 rather than zero. At the first decision node, Player I would anticipate Player II's reply, and would, therefore, choose *C* rather than *D*, to secure 2 rather than 1. This form of analysis, reasoning backward from the end, is called *backward induction* and is the basic method of finding subgame-perfect equilibria. In this game, it shows that the (*D*, *D*) equilibrium could not be reached by rational choice in the extensive form, and that means that it is imperfect in the normal form. By definition, a subgame-perfect equilibrium is one that induces payoff-maximizing choices in every branch or subgame of its extensive form.

In a further refinement, Selten [28] introduced the concept of the *trembling-hand equilibrium* to identify and eliminate imperfect equilibria. At every decision node in the extensive form or game tree, there is assumed to be a small probability ε (epsilon) that the player acts irrationally and makes a mistake. The introduction of these error probabilities, generated by a random process, produces a *perturbed game* in which every move that could be played has some positive probability of being played. Assuming that the players' trembling hands are common knowledge in a game, Selten proved that only the subgame-perfect equilibria of the original game remain equilibria in the perturbed game, and they continue to be equilibria as the probability ε tends to zero. According to this widely accepted refinement of the equilibrium concept, the standard game-theoretic rationality assumption (CKR2) is reinterpreted as a limiting case of incomplete rationality.

Experimental Games

Experimental games have been performed since the 1950s in an effort to understand the strategic interaction of human decision makers with bounded rationality and a variety of nonrational influences on their behavior (for detailed reviews, see [6, 11, 15, Chapters 1–4], [17, 25]). Up to the end of the 1970s,

experimental attention focused largely on the Prisoner's Dilemma and closely related games. The rise of behavioral economics in the 1980s led to experiments on a far broader range of games – see [4, 5].

The experimental data show that human decision makers deviate widely from the rational prescriptions of orthodox game theory. This is partly because of bounded rationality and severely limited capacity to carry out indefinitely iterated recursive reasoning ('I think that you think that I think...') (see [8, 14, 29]), and partly for a variety of unrelated reasons, including a strong propensity to cooperate, even when cooperation cannot be justified on purely rational grounds [7].

Evolutionary Game Theory

The basic concepts of game theory can be interpreted as elements of the theory of natural selection as follows. Players correspond to individual organisms, strategies to organisms' genotypes, and payoffs to the changes in their Darwinian fitness – the numbers of offspring resembling themselves that they transmit to future generations. In evolutionary game theory, the players do not choose their strategies rationally, but natural selection mimics rational choice. Maynard Smith and Price [20] introduced the concept of the *evolutionarily stable strategy* (ESS) to handle such games. It is a strategy with the property that if most members of a population adopt it, then no mutant strategy can invade the population by natural selection, and it is, therefore, the strategy that we should expect to see commonly in nature. An ESS is invariably a symmetric Nash equilibrium, but not every symmetric Nash equilibrium is an ESS.

The standard formalization of ESS is as follows [19]. Suppose most members of a population adopt strategy *I*, but a small fraction of mutants or invaders adopt strategy *J*. The expected payoff to an *I* individual against a *J* individual is written $E(I, J)$, and similarly for other combinations strategies. Then, *I* is an ESS if *either* of the conditions (1) or (2) below is satisfied:

$$E(I, I) > E(J, I) \quad (1)$$

$$E(I, I) = E(J, I), \text{ and } E(I, J) > E(J, J) \quad (2)$$

Condition (1) or (2) ensures that J cannot spread through the population by natural selection. In addition, differential and difference equations called *replicator dynamics* have been developed to model the evolution of a population under competitive selection pressures. If a population contains k genetically distinct types, each associated with a different pure strategy, and if their proportions at time t are $x(t) = (x_1(t), \dots, x_k(t))$, then the replicator dynamic equation specifies the population change from $x(t)$ to $x(t+1)$.

Evolutionary game theory turned out to solve several long-standing problems in biology, and it was described by Dawkins as ‘one of the most important advances in evolutionary theory since Darwin’ [9, p. 90]. In particular, it helped to explain the evolution of cooperation and altruistic behavior – conventional (ritualized) rather than escalated fighting in numerous species, alarm calls by birds, distraction displays by ground-nesting birds, and so on.

Evolutionary game theory is also used to study adaptive learning in games repeated many times. Evolutionary processes in games have been studied analytically and computationally, sometimes by running simulations in which strategies are pitted against one another and transmit copies of themselves to future generations in proportion to their payoffs (see [2, 3, Chapters 1, 2; 23, 24]).

Gauss, Johann Carl Friedrich

Born: April 30, 1777, in Brunswick, Germany.

Died: February 23, 1855, in Göttingen, Germany.

Born to humble means in the Duchy of Brunswick (now in Germany), Carl Friedrich Gauss's contributions spanned a lifetime and earned the epithet 'Prince of Mathematicians'. As a mathematical scientist, often ranked with Archimedes and Newton, Gauss is among the elite of any era. In 1784, he entered a Brunswick gymnasium that recognized his talent. By age 14, the Duke of Brunswick granted Gauss a stipend and he entered the Collegium Carolinum, where he studied modern languages as well as the works of Newton, Euler, and Lagrange. In 1795, he entered the University of Göttingen. Shortly thereafter, entries in Gauss's personal notebooks contained groundbreaking insights into number theory. Within a year, Gauss also constructed a 17-sided regular polygon using only ruler and compass – the first so constructed since antiquity. Gauss returned to Brunswick in 1798 and entered the University of Helmstedt, from which he earned a doctorate the following year. The dissertation, published in 1801, contains Gauss's first proof of the fundamental theorem of algebra. Also in 1801, without publishing his method, Gauss correctly predicted the location of the first-known, recently discovered asteroid, Ceres. His brilliance emerged at an early age.

Gauss's contributions to statistics revolve around the conceptual convergence known as the Gauss–Laplace synthesis. Occurring in the years following 1809, this foundational merger advanced effective methods for combining data with the ability to quantify error. Gauss's role in this synthesis centers in his account of least squares, his use of the normal curve, and the influence this work had on **Pierre-Simon Laplace**.

During the mid-seventeenth century, astronomers wanted to know how best to combine a number of independent but varying observations of the same phenomenon. Among the most promising procedures was the method of least squares (*see* **Least Squares Estimation**), which argues that the minimal distance to the true value of a distribution of observations is the sum of squared deviations from the mean. In

1807, Gauss became director of the University of Göttingen's observatory. Despite early applications of least squares insights, Gauss failed to publish an account until 1809, and even then only in the last chapter of a major contribution to celestial mechanics [2]. A priority dispute arose with Adrien Marie Legendre, who first published a least squares discussion in 1805.

However, the respect afforded Gauss always gave pause to quick dismissals of his priority claims. Even if least squares publication priority belongs to Legendre, Gauss offered a sophisticated elaboration of the method. In addition to developing least squares, the 1809 publication contained another seminal contribution to statistics, that is, use of the normal distribution to describe measurement error. Here, Gauss employed Laplace's probability curve for sums and means to describe the measurement of random deviations around the true measurement of an astronomical event. Because of this insight, by the end of the nineteenth century, what we know today as the normal distribution came to be known as the Gaussian distribution. Although Gauss was not the first to describe the normal curve, he was the first to use it to assign precise probabilities to errors. In honor of this insight, the 10 Deutschmark would one day bear both an image of Gauss and the normal curve's geometric and formulaic expression.

The 1809 Gaussian insights proved a conceptual catalyst. In 1810, Laplace presented what we know today as the **central limit theorem**: the distribution of any sufficiently sampled variable can be expressed as the sum of small independent observations or variables approximating a normal curve. When Laplace read Gauss's 1809 book later that year, he recognized the connection between his theorem, the normal distribution, and least squares estimates. If errors are aggregates, then errors should distribute along the normal curve with least squares providing the smallest expected error estimate. The coming years were a conceptual watershed as additional work by Gauss, Laplace, and others converged to produce the Gauss–Laplace synthesis. As Youden ([5], p. 55) later observed "The normal law of error stands out... as one of the broadest generalizations of natural philosophy... It is an indispensable tool for the analysis and the interpretation of the basic data obtained by observation and experiment". Following 1809, these insights spread from astronomy to physics and the military. Absorption into the social sciences

took more time. By the time the use of least squares flowered in the social sciences, **Galton**, **Pearson**, and **Yule** had uniquely transformed the procedure into the techniques of regression (*see* **Multiple Linear Regression**) and **analysis of variance** [3, 4].

In addition to the Gauss–Laplace synthesis, Gauss’s more general contributions include the fundamental theorems of arithmetic and algebra and development of the algebra of congruence. He published important work on actuarial science, celestial mechanics, differential geometry, geodesy, magnetism, number theory, and optics. He invented a heliotrope, magnetometer, photometer, and telegraph. *Sub rosa*, he was among the first to investigate non-Euclidean geometry and, in 1851, approved Riemann’s doctoral thesis. Indeed a titan of science [1], Gauss was extraordinarily productive throughout his life, although his personal life was not without turmoil. After developing heart disease, Gauss died in his sleep in late February, 1855.

Gene-Environment Correlation

Nature versus Nurture

The history of behavioral sciences has been plagued by a seeming rivalry between genetic influences and environmental influences as the primary determinant of behavior. Today, there is widespread support for the idea that most behavior results from a complex interaction of genetic and environmental effects (*see Gene-Environment Interaction*). However, it is a mistake to assume that these effects are independent sources of influence. Much of an individual's environment is not random in nature; rather, genes can influence an individual's exposure to certain environments, how that individual experiences the environment, and the degree of influence that certain environments exert [2, 13]. This phenomenon is called *gene-environment correlation*. It refers to the fact that an individual's environment is influenced by their genetic predispositions, making genes and the environment inexorably entwined.

Three specific ways by which genes may exert an effect on the environment have been delineated [9, 14]: (a) Passive gene-environment effects refer to the fact that among biologically related relatives (i.e., nonadoptive families), parents provide not only their child's genotypes, but also their rearing environment. Therefore, the child's genotype and home environment are correlated. (b) Evocative gene-environment effects refer to the idea that individual's genotypes influence the responses they receive from others. For example, a child who is predisposed to having an outgoing, cheerful disposition might be more likely to receive positive attention from others than a child who is predisposed to timidity and tears. A person with a grumpy, abrasive temperament is more likely to evoke unpleasant responses from coworkers and others with whom they interact. Thus, evocative gene-environment effects can influence the way an individual experiences the world. (c) Finally, active gene-environment effects refer to the fact that an individual actively selects certain environments and takes away different things from his/her environment, and these processes are influenced by an individual's genotype. Therefore, an individual predisposed to high sensation-seeking may be more prone to attend

parties and meet new people, thereby actively influencing the environments he/she experiences.

Evidence exists in literature for each of these processes. Support for passive gene-environment effects can be found in a study of more than 600 adoptive families recruited from across the United States [6]. Comparisons of adoptive and biological children's correlations between family functioning and adolescent outcome are informative for examining passive gene-environment effects, because only biological children share genes with their parents and are affected by these passive gene-environment effects (both will be affected by evocative and active gene-environment effects). Correlations between mother ratings of family functioning and child ratings of adjustment were substantially higher in biological offspring than in adoptive offspring, supporting passive gene-environment correlation.

The adoption design (*see Adoption Studies*) has also been used to examine evocative gene-environment effects [7]. With data from the Colorado Adoption Project, adoptive children who were or were not at genetic risk for antisocial behavior, based on their biological mother's antisocial history, were compared. Children who were at risk for antisocial behavior consistently evoked more negative control, as self-reported by their adoptive parents, than did adoptees not at risk, from age 5 to 12. These results suggest an evocative gene-environment effect. Children who were genetically predisposed to higher levels of antisocial behavior displayed more externalizing behavior, which evoked more negative control responses from their parents.

Finally, support for active gene-environment effects can be found in another type of study. In order to study active gene-environment effects, one must study individuals outside the home, to assess the degree to which genes may be actively influencing an individual's selection of various environmental niches [14]. As part of the **Nonshared Environment** in Adolescent Development project, genetic influences on individuals' social interactions with peers and teachers were assessed using a twin, full-sibling, and step-sibling design [5]. Significant genetic influence was found for adolescents' reports of positive interactions with friends and teachers. Additionally, **heritability** estimates were quite high for parents' reports of peer group characteristics, suggesting active gene-environment effects in which an

2 Gene-Environment Correlation

individual's genotype influenced the group of individuals they selected as peers. Peer environments are known to then play a significant role in adolescent outcomes [1].

A number of other findings exist supporting genetic influence on environmental measures. Substantial genetic influence has been reported for adolescents' reports of family warmth [10–12]. Genes have been found to influence the degree of anger and hostility that children receive from their parents [11]. They influence the experience of life events [2, 3], and exposure to trauma [4]. In fact, genetic influence has been found for nearly all of the most widely used measures of the environment [8]. Perhaps, even more convincing is that these environmental measures include not only reports by children, parents, and teachers, but also observations by independent observers [11].

Thus, many sources of behavioral influence that we might consider 'environmental' are actually under a degree of genetic influence. An individual's family environment is correlated with their genotype when they are reared among biological relatives. Furthermore, genes influence an individual's temperament and personality, which impacts both the way that other people react to the individual and the environments that person seeks out and experiences. Thus, environmental experiences are not always random, but can be influenced by a person's genetic predispositions. It is important to note that in standard **twin designs**, the effects of gene-environment correlation are included in the genetic component. For example, if genetic influences enhance the likelihood that delinquent youth seek out other delinquents for their peers, and socialization with these peers further contributes to the development of externalizing behavior, that effect could be subsumed in the genetic component of the model, because genetic effects led to the risky environment, which then influenced behavioral development. Thus, genetic estimates may represent upper bound estimates of direct genetic effects on the disorders because they also include gene-environment correlation effects.

Gene-Environment Interaction

Gene x environment interaction, or GxE, as it is commonly called in behavioral genetic literature, is the acknowledgement that genetic and environmental influences on behaviors and traits do not act additively and independently, but may instead be dependent upon one another. One of the working hypotheses among researchers is the diathesis-stress model [7], whereby genetic variants confer an underlying diathesis, or vulnerability to a certain behavior or trait. These genetic vulnerabilities may only impact upon development when accompanied by a specific environmental stressor. Other hypotheses for GxE interactions include the protective effect of genetic variants on environmental risk, and genetic sensitivity to environmental exposure. There are three main strategies for assessing GxE interactions in behavioral genetic research, primarily through the use of **adoption studies**, **twin studies**, and studies of genotyped individuals. Each method has its relative strengths and weaknesses.

The Adoption Study Method

Some of the earliest examples of gene x environment interaction appear in the adoption literature in the early 1980s. Theoretically, adoption studies are ideal methods for assessing GxE, as they allow for a clean separation of genetic influence (via the biological parent characteristics) from salient environmental characteristics (defined by adoptive parent characteristics). Figure 1 shows an example of gene x environment interaction using the adoption design for the development of adolescent antisocial behavior [1]. In this study, genetic risk was defined as the presence of alcoholism or antisocial behavior in the biological parent, and environmental risk was defined as being raised in an adoptive family with significant psychopathology in adoptive siblings or parents, and/or the presence of adoptive parent marital separation or divorce. Standard multivariate regression analyses (*see* **Multivariate Multiple Regression**) were performed assessing the independent effects of genetic and environmental risk, as

Figure 1 Least-squares means ($\pm$ SE) for simple genetic, environmental, and interaction effects (Iowa 1980 data; $N = 367$). (Figure reproduced from Kluwer Academic Publishers Behavior Genetics, **13**, 1983, p. 308, *Evidence for Gene-environment Interaction in the Development of Adolescent Antisocial Behavior*, R.J. Cadoret, C.A. Cain, and R.R. Crowe, Figure 1, copyright 1983, Plenum Publishing Corporation, with kind permission of Springer Science and Business Media)

well as the interaction term between the two variables. Figure 1 illustrates that neither the presence of genetic risk nor the presence of environmental risk was sufficient, in and of itself, to cause an increase in the average number of antisocial behaviors in adolescent adoptees, compared with adoptees with neither genetic nor environmental risk. In contrast, the presence of *both* genetic and environmental risk factors was related to a higher mean number of antisocial behaviors, compared to all other groups.

Adoption studies have the advantage over other methods that use samples of related individuals of being able to more cleanly separate genetic risk from environmental risk, as adoptees typically have limited or no contact with their biological parents. Thus, in theory, genetic risk in the biological parent is unlikely to be correlated with environmental risk in the adoptive home environment via passive gene-environment

correlation. However, as shown in more recent studies, results from adoption studies can still potentially be confounded by evocative **gene-environment correlation**. For example, Ge et al. [4] reported that hostile and aggressive parenting from the adoptive parent was, in fact, correlated with psychopathology in the biological parent. This relationship was largely mediated through the adoptees' own hostile and aggressive behavior, demonstrating that gene-environment correlation can occur when adoptive parents respond to the behavior of their adopted child (which is, in turn, partly influenced by genetic factors). Thus, genetic-influenced behaviors of the adoptee can evoke a gene-environment correlation. Other limitations to the adoption study method have typically included: (1) the fact that adoptive parents are screened prior to placement, indicating that the range of environmental factors within adoptive samples is likely to be truncated, and that severe environmental deprivation therefore is unlikely; and (2) the limited generalizability of results from adoptive samples to the general population (*see Adoption Studies*).

The Twin Study Method

Twin studies typically estimate the proportion of variation in a given behavior or trait that is due to latent genetic and environmental factors (*see ACE Model*). In GxE studies using twin samples, the central question is generally whether genetic variation on behavior or traits changes across some level of a measured environmental variable. Methods to assess GxE interaction in twin studies include extensions of the DeFries–Fulker regression model (*see DeFries–Fulker Analysis*), testing whether heritabilities (*see Heritability*) are the same or different among individuals in two different groups (e.g., the finding that the heritability of alcohol use is higher among unmarried vs. married women [5]), or through the inclusion of a measured environmental variable as a continuous moderator of genetic and environmental influences in the standard *ACE model*. Examples of replicated GxE interactions using twin data include the finding that the heritability of cognitive ability is greater among adolescents from more advantaged socioeconomic backgrounds [9, 11]. In both of these studies, the absolute magnitude of shared environmental influences on variation was stronger among adolescents from poorer and/or less educated homes.

Conversely, the absolute magnitude of genetic variation was greater among adolescents from higher socioeconomic status families. Both of these factors contributed to the finding that the heritability of cognitive ability (which is defined as the proportion of phenotypic variance attributed to genetic factors) was higher among adolescents in more educated homes.

Advantages to the twin method include the fact that these studies call into question the assumption that heritability is a constant, and can identify salient aspects of the environment that may either promote or inhibit genetic effects. In addition, there are many large twin studies in existence, which make replication of potential GxE interactions possible. The primary disadvantage to this method is that genetic factors are defined as latent variables. Thus, these studies cannot identify the specific genetic variants that may confer greater or lesser risk at different levels of the environment.

Studies of Genotyped Individuals

Arguably, perhaps the 'gold standard' for assessing GxE interaction are studies that investigate whether a specific genetic variant interacts with a measured environmental characteristic. One of the first examples of these studies is the finding that a polymorphism in the monoamine oxidase A (MAOA) gene interacts with child maltreatment to influence mean levels of antisocial behavior [2]. Figure 2 shows the relevant results from this study for four measures of antisocial behavior. As can be seen in this figure, maltreated children with the genetic variant of the MAOA gene that confers high levels of MAOA activity showed mean levels of antisocial behavior that were not significantly different from mean levels of antisocial behavior among non-maltreated children, indicating that this genetic variant had a protective influence against the effects of child maltreatment. Interestingly, although there was a main effect of child maltreatment in these analyses, there was no main effect of the MAOA genotype, indicating that genetic variants that confer low levels of MAOA activity are not, in and of themselves, a risk factor for antisocial behavior.

Advantages to this method are many. Analysis is relatively straightforward, requiring simply the use of multivariate regression techniques. Studies can be done using any sample of genotyped

Figure 2 The association between childhood maltreatment and subsequent antisocial behavior as a function of *MAOA* activity. (a) Percentage of males (and standard errors) meeting diagnostic criteria for Conduct Disorder between ages 10 and 18. In a hierarchical logistic regression model, the interaction between maltreatment and *MAOA* activity was in the predicted direction, $b = -0.63$, $SE = 0.33$, $z = 1.87$, $P = 0.06$. Probing the interaction within each genotype group showed that the effect of maltreatment was highly significant in the low-*MAOA* activity group ($b = 0.96$, $SE = 0.27$, $z = 3.55$, $P < 0.001$), and marginally significant in the high-*MAOA* group ($b = 0.34$, $SE = 0.20$, $z = 1.72$, $P = 0.09$). (b) Percentage of males convicted of a violent crime by age 26. The $G \times E$ interaction was in the predicted direction, $b = -0.83$, $SE = 0.42$, $z = 1.95$, $P = 0.05$. Probing the interaction, the effect of maltreatment was significant in the low-*MAOA* activity group ($b = 1.20$, $SE = 0.33$, $z = 3.65$, $P < 0.001$), but was not significant in the high-*MAOA* group ($b = 0.37$, $SE = 0.27$, $z = 1.38$, $P = 0.17$). (c) Mean z scores ($M = 0$, $SD = 1$) on the Disposition Toward Violence Scale at age 26. In a hierarchical ordinary least squares (OLS) regression model, the $G \times E$ interaction was in the predicted direction ($b = -0.24$, $SE = 0.15$, $t = 1.62$, $P = 0.10$); the effect of maltreatment was significant in the low-*MAOA* activity group ($b = 0.35$, $SE = 0.11$, $t = 3.09$, $P = 0.002$) but not in the high-*MAOA* group ($b = 0.12$, $SE = 0.07$, $t = 1.34$, $P = 0.17$). (d) Mean z scores ($M = 0$, $SD = 1$) on the Antisocial Personality Disorder symptom scale at age 26. The $G \times E$ interaction was in the predicted direction ($b = -0.31$, $SE = 0.15$, $t = 2.02$, $P = 0.04$); the effect of maltreatment was significant in the low-*MAOA* activity group ($b = 0.45$, $SE = 0.12$, $t = 3.83$, $P = 0.001$) but not in the high-*MAOA* group ($b = 0.14$, $SE = 0.09$, $t = 1.57$, $P = 0.12$). (Reprinted with permission from Caspi et al. (2002). *Role of Genotype in the Cycle of Violence in Maltreated Children*. Science, **297**, 851–854. Copyright 2002 AAAS)

individuals – there is no special adoptive or family samples required. Because these studies rely on measured genotypes, they can pinpoint more precisely the genetic variants and the potential

underlying biological mechanism that confer risk or protective effects across different environments. On the other hand, the effects of any one individual gene (both additively and/or interactively)

on variation in behavior or traits is likely to be quite small, which may limit the power to detect such interactions in these studies, and may further require some *a priori* knowledge of how specific genes may influence behavior or traits. In addition, because genotypes are inherited from parents, there may be significant gene-environment correlations that bias the interpretation of results (see Rutter & Silberg [10] and Purcell [8] for discussion of methodological issues in assessing GxE interactions in the presence of gene-environment correlation).

Conclusions

Recent behavioral genetic studies have taken a much-needed departure from standard studies of additive genetic and environmental influences on variation in human development by both acknowledging and testing for the interaction between genes and environments. Although these issues have a long history in behavioral genetic thinking [3, 6, 7], it is only more recently, with statistical, methodological, and molecular genetic advances, that these interesting research questions about gene-environment interplay have become tractable. The three methods reviewed rely on different means of assessing genetic influence. Specifically, adoption designs rely on the presence of high-risk phenotypes in biological parents of adoptees to assess genetic risk, traditional twin studies estimate changes in genetic influence as measured at the latent trait level, and studies of genotyped individuals focus on specific genetic variants. Nonetheless, all three methods require the inclusion of measured variables in the analyses, suggesting that behavioral genetic researchers should continue to include and refine their definitions of possible environmental influences on behavior, so that these more interesting and complex questions of gene x environment interaction can be explored.

Generalizability

Due to various limitations in necessary resources, researchers generally study a phenomenon in a specific setting, and then try to generalize the obtained results to other settings. So, for example, while a target population may be infinite, the study sample will be a small (finite) subset of this target population. The degree to which the results of a study can be generalized from one setting to other settings is referred to as ‘generalizability’. Here, we will first present a set of commonly accepted rules for generalizing information, and then we will discuss the applications of these rules in behavioral sciences. We will then argue that the presented rules are subject to many exceptions, and that generalization requires abstraction, and depends on the human thought process, rather than being a mechanistic or statistical process [6].

There are some commonly accepted rules for generalizability of information. We will discuss three. First, a prerequisite for generalizability of the results is that the results of the study be valid within the study population (**internal validity**) [1, 2]. Consider, for example, a study comparing the efficacy of treatments *A* and *B*, in which the researchers allocate all, or even most, of the patients with a good prognosis to treatment *A*. Such a comparison is obviously invalid even internally, and so generalization of its results would be irrelevant, the possibility of a sampling bias that precisely compensates for this allocation bias [2] notwithstanding. To enhance the internal validity of studies, researchers often select a homogeneous group of humans or animals as their study population. Often, however, such a homogeneous population is not representative of the target population.

The extent to which a study population is homogeneous is usually a trade-off between the quest for internal validity and representativeness; hence, making a decision about the study population is usually a personal judgment of the researcher. Bench scientists and animal researchers tend to emphasize higher internal validity, while social and behavioral scientists and epidemiologists tend to prefer enhanced representativeness to enhanced internal validity.

Second, experience has shown that the more similar (among units in the target population) the contributors to the causal pathway are, the more reproducible the results will be. Physical phenomena are generally highly reproducible; for example, an

experiment conducted to measure the acceleration of a falling object due to gravity will likely obtain results that generalize to anywhere (on earth, at least). Likewise for an experiment performed to determine the freezing point of water, which will depend on pressure, but little else. If it is known that pressure matters, then it can be controlled for. Biologic phenomena tend to be more easily generalized from population to population than social or behavioral phenomena can be.

Third, in human studies, there is an important difference between generalizability of results of surveys and generalizability of results of association studies [6, 7]. In surveys, the target population is usually well defined. For the results of a survey to be generalizable, then, the study population must be representative of this well-defined target population. For this purpose, one usually selects a sufficiently large random sample, which confers confidence in the extent to which the sample is representative of the target population, with respect to both known and unknown factors. There are a few caveats worthy of mention. For one thing, the population from which the sample is randomly selected tends to differ from the target population. This forces one to consider not only the degree to which the sample represents the sampled population, but also the degree to which the sampled population represents the target population, and, ultimately, the degree to which the sample represents the target population.

Years ago, when telephones were not ubiquitous, telephone surveys tended to create biases in that they would overrepresent those wealthy enough to afford telephones. This would create a problem only if the target population included those without telephones. A famous example of this type of phenomenon occurred during the presidential race of 1936, when *The Literary Digest* mistakenly oversampled Republicans, and confidently predicted that Alf Landon would beat Franklin Roosevelt and win the presidency. Sometimes, the distortion between the sampled population and the target population is created intentionally, as when a run-in is used prior to a randomized trial for the purposes of excluding those subjects who do not respond well to the active treatment offered during the run-in [2]. This step can help create the illusion of a treatment effect.

Another consideration is the distinction between randomized and representative. It is true that a random sample may be used in hopes of creating

2 Generalizability

a representative sample, but if presented with a sample, one could check the extent to which this sample represents the target population (assuming that characteristics of this target population are also known). Having gone through the step of assessing the extent to which the sample is representative of the target population, would one then care if this sample were obtained at random? Certainly, other sampling schemes, such as convenience sampling, may create a sample that appears to represent the target population well, at least with respect to the dimensions of the sample that can be checked. For example, it may be feasible to examine the gender, age, and annual salary of the study subject for representativeness, but possibly not their political belief. It is conceivable that unmeasured factors contribute to results of survey questions, and ignoring them may lead to unexpected errors. From this perspective, then, randomization does confer added benefits beyond those readily checked and classified under the general heading of representativeness.

Of course, one issue that remains, even with a sample that has been obtained randomly, is a variant of the Heisenberg uncertainty principle [1]. Specifically, being in the study may alter the subjects in ways that cannot be measured, and the sample differs from the population at large with respect to a variable that may assume some importance. That is, if X is a variable that takes the value 1 for subjects in the sample, and the value 0 for subjects not in the sample, then the sample differs from the target population maximally with respect to X . Of course, prior to taking the sample, each subject in the target population had a value of $X = 0$, but for those subjects in the sample, the value of X was changed to 1, in time for X to exert whatever influence it may have on the primary outcomes of the study. This fact has implications for anyone not included in a survey.

If, for example, a given population (say male smokers over the age of 50 years) is said to have a certain level of risk regarding a given disease (say lung cancer), then what does this mean to a male smoker who was not included in the studies on which this finding was based? Hypothetically, suppose that this risk is 25%. Does this then mean that each male smoker over 50, whether in the sample or not, has a one in four chance of contracting lung cancer? Or does it mean that there is some unmeasured variable, possibly a genetic mutation, which we will call a predisposition towards lung cancer (for lack of a

better term), which a quarter of the male smokers over 50 happens to have? Presumably, there is no recognizable subset of this population, male smokers over 50, which would allow for greater separation (as in those who exercise a certain amount have 15% risk while those who do not have 35% risk).

Suppose, further, that one study finds a 20% risk in males and a 35% risk in smokers, but that no study had been done that cross-classified by both gender and smoking status. In such a case, what would the risk be for a male smoker? The most relevant study for any given individual is a study performed in that individual, but the resources are not generally spent towards such studies of size one. Even if they were, the sample size would still be far too small to study all variables that would be of interest, and so there is a trade-off between the specificity of a study (for a given individual or segment of the population) and the information content of a study.

In contrast to surveys, association studies require not only that the sample be representative of the study population but also that it be homogeneous. As mentioned previously, the use of run-ins, prior to randomization, to filter out poor responders to an active treatment creates a distortion that may result in a spurious association [2]. That is, there may well be an association, among this highly select group of randomized subjects who are already known to respond well to the active treatment, between treatment received and outcome, but this association may not reflect the reality of the situation in the population at large. But even if the sample is representative of the target population, there is still a risk of spurious association that arises from pooling heterogeneous segments of the population together. Suppose, for example, that one group tends to be older and to smoke more than another group, but that within either group there is no association between smoking status and age. Ignoring the group, and studying only age and smoking status, would lead to the mistaken impression that these two variables are positively associated. This is the ecological fallacy [5].

When trying to generalize associations in behavioral sciences, one needs to consider different characteristics of exposure, effect modifiers, confounders, and outcome. Duration, dose, route, and age at exposure may all be important. In general, extrapolating the results obtained from a certain range of exposure to values outside that range may be very misleading. While short-term low-dose stress may be

stimulating, very high levels of stress may inhibit productivity. Effect modifiers may vary among different populations. Single parenthood may be a stigma in some societies, and, therefore, may lead to behavioral abnormalities in the children. However, societies that show high support for single parent families may modify and lower such detrimental effects. Differences in the distribution of confounding factors result in failure of replication.

For example, higher education may be associated with higher income in some societies, but not in others. A clear definition of exposure and outcome is necessary, and these definitions should be maintained when generalizing the results. Sufficient variability in both exposure and outcome is also important. Family income may not be a predictor of future educational success when studied in a select group of families that all have an annual income between \$80 000–100 000, but it may be a strong predictor in a wider range of families.

Despite the fact that the term ‘generalizability’ is frequently used, and the rules mentioned above are commonly taught in methodology classes, the meaning of generalizability is often not clear, and these rules give us only a vague idea about how and when we are allowed to generalize information. One reason for such vagueness is that generalizability is a continuum rather than a dichotomous phenomenon, and the degree of acceptable similarity is not well defined. For example, suppose that in comparing treatments *A* and *B* for controlling high blood pressure, treatment *A* is more effective by 20 mmHg on average

in one population, but only 10 mmHg more effective on average in another population. Although treatment *A* is better than treatment *B* in both populations, the magnitude of the blood pressure reduction is different. Are the results obtained from one population generalizable to the other? There is no clear answer. Despite centuries of thinking and examination, the process of synthesis of knowledge from individual observations is not well understood [3, 4, 6]. This process is neither mechanical nor statistical; that is, the process requires abstraction [7].

Generalizability Theory: Basics

From a practical perspective, scientists have always been interested in quantifying **measurement errors**. Regardless of the professional discipline, be it psychology, biology, sociology, medicine, and so on, gathering measurements and determining their precision is a fundamental task. A testing agency would certainly want to know the precision of any ability estimates, and which measurement conditions (e.g., test length, number of raters) best achieved the goal of obtaining valid and reliable examinee scores. For these studies and programs, and many others, there is often a fundamental need to ascertain the degree of measurement error that is involved in the process of gathering data. Once this is accomplished, one can then tailor the data-gathering process to minimize potential errors, thereby enhancing the precision of the measures.

Historically, classical test theory (CTT) (*see Classical Test Models*) [15] was employed as a framework for understanding and quantifying measurement errors. In CTT, a person's observed score (X) is made up of 'true' (T) component and error (E). The reliability of a measure (r_{xx}) is simply the ratio of true score variance (σ^2_{true}) to observed score variance ($\sigma^2_{\text{observed}}$). True scores and true score variances are typically estimated via methods such as internal consistency and test-retest. If there is no error in the measurement process, then the observed and 'true' measurement will be the same, reflecting perfect reliability. For most real-world measurement problems, this is unlikely to be the case. More important, an undifferentiated E is frequently of little value except to quantify the consistencies and inconsistencies in the data. From a practical perspective, it is often essential to know the exact conditions of measurement needed for acceptably precise measurement. To do this, one must be able to determine, quantify, and study multiple potential sources of error.

Generalizability (G) theory (*see Generalizability Theory: Overview*) offers a broad conceptual framework and associated statistical procedures for investigating various measurement issues. Unlike CTT, generalizability theory does not conceptualize measurement error as a unitary concept. Error can be attributed to multiple sources, and experiments can

be devised to estimate how much variation arises from each source. In effect, generalizability theory liberalizes, or extends, CTT. **Analysis of variance (ANOVA)** is used to disentangle multiple sources of error that contribute to the unitary E in CTT. As a result, generalizability analyses can be used to understand the relative importance of various sources of error and to define efficient measurement procedures. It should be noted, however, that although generalizability theory is rooted in ANOVA-type designs, there are key differences in emphasis (e.g., estimation of variance components as opposed to tests of statistical significance) and terminology.

While the conceptual framework for generalizability theory is relatively straightforward, there are some unique features that require explanation. These include universes of admissible observations, G (generalizability) studies, universes of generalization, D (decisions) studies, and universe scores. The universe of admissible observations for a particular measure is based on what the decision-maker is willing to treat as interchangeable for the purposes of making a decision. It is characterized by the sources of variation in universe scores (expected value of observations for the person in the stated universe) that are to be explicitly evaluated. For example, a researcher may be interested in evaluating the clinical skills of physicians. To do this, he/she could identify potential performance exercises (e.g., take a patient history, perform a required physical examination) and observers (physician, or expert, raters). For this hypothetical investigation, the universe of admissible observations contains an exercise, or task, facet (take a history, perform a physical examination) and a rater facet. If any of the tasks (t) could be paired with any of the raters (r), then the universe of admissible observations is said to be crossed (denoted $t \times r$). In generalizability theory, the term universe is reserved for conditions of measurement, and is simply the set of admissible observations to which the decision maker would like to generalize. The word population is used for objects of measurement. In the example noted above, the researcher would also need to specify the population (i.e., persons to be evaluated). The next step would be to collect and analyze data to estimate the relevant **variance components**. This is known as a G (generalizability) study. For example, one could envision a design where a sample of raters (n_r) evaluates the performances of a sample of persons (n_p) on a sample of clinical exercises, or

2 Generalizability Theory: Basics

tasks (n_t). This is a two-facet design and is denoted $p \times t \times r$ (person by task by rater). Where each level of one facet (rater) is observed in combination with each level of the other (task), the result is a crossed design. If levels of one facet are observed in combination with specific level(s) of another, the design is said to be nested. For example, variance components can be estimated for people, tasks, raters, and the associated interactions. These components are simply estimates of differences in scores attributable to a given facet or interaction of sources.

The purpose of a G study is to obtain estimates of variance components associated with the universe of admissible observations. These estimates can be used in D (decision) studies to design efficient measurement procedures. For D studies, the researcher must specify a universe of generalization. This could contain all facets in the universe of admissible observations (e.g., $p \times T \times R$; for D study designs, facets are typically denoted by capital letters) or be otherwise restricted. For the scenario above, one may want to generalize persons' scores based on the specific tasks and raters used in the G study to persons' scores for a universe of generalization that involves many other tasks and raters. The sample sizes in the D study (n'_t, n'_r) need not be the same as the sample sizes in the G study (n_t, n_r). Also, the focus of the D study is on mean scores for persons rather than single person by task by rater observations. If a person's score is based on his or her mean score over $n'_t n'_r$ observations, the researcher can explore, through various D studies, the specific conditions that can make the measurement process more efficient.

It is conceivable to obtain a person's mean score for every instance of the measurement procedure (e.g., tasks, raters) in the universe of generalization. The expected value of these mean scores in the stated universe is the person's universe score. The variance of universe scores over all persons in the population is called the *universe score variance*. More simply, it is the sum of all variance components that contribute to differences in observed scores. Universe score variance is conceptually similar to true score variance (T) in classical test theory.

As mentioned previously, once the G study variance components are estimated, various D studies can be completed to determine the optimal conditions for measurement. Unlike CTT, where observed score variance can only be partitioned into two parts (σ^2_{true} and $\sigma^2_{\text{observed}}$), generalizability theory affords

the opportunity to further partition error variance. More important, since some error sources are only critical with respect to relative decisions (e.g., rank ordering people based on scores), and others can influence absolute decisions (e.g., determining mastery based on defined standards or cutoffs), it is essential that they can be identified and disentangled. Once this is accomplished, both error 'main effects' and error 'interaction effects' can be studied. For example, in figure-skating, multiple raters are typically used to judge the performance of skaters across multiple programs (short, long). Measurement error can be introduced as a function of the choice of rater, the type of program (task), and, most important, the interaction between the two. For this situation, if we accept that any person in the population can participate in any program in the universe and can be evaluated by any rater in the universe, the observable score for a single program evaluated by a single rater can be represented:

$$X_{\text{ptr}} = \mu + \nu_p + \nu_t + \nu_r + \nu_{pt} + \nu_{pr} + \nu_{tr} + \nu_{\text{ptr}}. \quad (1)$$

For this design, μ is the grand mean in the population and universe and ν specifies any one of the seven components. From this, the total observed score variance can be decomposed into seven independent variance components:

$$\begin{aligned} \sigma^2(X_{\text{ptr}}) = & \sigma^2_{(p)} + \sigma^2_{(t)} + \sigma^2_{(r)} + \sigma^2_{(pt)} \\ & + \sigma^2_{(pr)} + \sigma^2_{(tr)} + \sigma^2_{(\text{ptr})} \end{aligned} \quad (2)$$

The variance components depicted above are for single person by programs (tasks) by rater combinations. From a CTT perspective, one could collapse scores over the raters and estimate the consistency of person scores between the long and short programs. Likewise, one could collapse scores over the two programs and estimate error attributable to the raters. While these analyses could prove useful, only generalizability theory evaluates the interaction effects that introduce additional sources of measurement error.

In generalizability theory, reliability-like coefficients can be computed both for situations where scores are to be used for relative decisions and for conditions where absolute decisions are warranted. For both cases, relevant measurement error variances (determined by the type of decision, relative or absolute) are pooled. The systematic variance (universe score variance) is then divided by the sum of the

systematic and the measurement error variance to estimate reliability. When relative decisions are being considered, only measurement error variances that could affect the rank orderings of the scores are important. For this use of scores, the ratio of systematic variance to the total variance, known as a generalizability coefficient ($E\rho^2$), is the reliability estimate. This is simply a quantification of how well persons' observed scores correspond to the universe scores. When absolute decisions are considered (i.e., where scores are interpreted in relation to a standard or cutoff), all the measurement error variances can impact the reliability of the scores. Here, the reliability coefficient, Phi (Φ), is also calculated as the ratio of systematic variance to total variance. If all the measurement error variances that are uniquely associated with absolute decisions are zero, then the generalizability and Phi coefficients will be equal.

The defining treatment of generalizability theory is provided by Cronbach et al. [10]. Brennan provides a history of the theory [2]. For the interested reader, there are numerous books and articles, both technical and nontechnical, covering all aspects of the theory [17].

Purpose

The purpose of this entry is to familiarize the reader with the basic concepts of generalizability theory. For the most part, the treatment is nontechnical and concentrates on the utility of the theory and associated methodology for handling an assortment of measurement problems. In addition, only univariate models are considered. For more information on specific estimation procedures, multivariate specifications, **confidence intervals** for estimated variance components, and so on, the reader should consult Brennan [3]. For this entry, the basic concepts of generalizability theory are illustrated through the analysis of assessment data taken from an examination developed to evaluate the critical-care skills of physicians [1].

Measurement Example

Fully Crossed Design

The data for this example came from a performance-based assessment, designed to evaluate the emergency

care skills of physicians training in anesthesiology. The assessment utilized a sensorized, life-size electromechanical patient mannequin that featured, amongst other things, breath sounds, heart sounds, and pulses. Computer-driven physiologic and pharmacologic models determine cardiac and respiratory responses, and are used to simulate acute medical conditions. The simulator offers simple as well as advanced programming actions to create and then save a unique scenario for repeated evaluation of performances. A variety of additional features (e.g., heart rate, lung compliance, vascular resistance) can be manipulated independently to create a unique, but reproducible event that effectively tests the skill level of the medical provider. Six acute care scenarios (cases) were developed. Each simulated scenario was constructed to model a medical care situation that required a rapid diagnosis and acute intervention in a brief period of time.

Twenty-eight trainees were recruited and evaluated. Each of the 28 participants was assessed in each of the six simulated scenarios. Each trainee's performance was videotaped and recorded. Three raters independently observed and scored each of the performances from the videotaped recordings. A global score, based on the time to diagnosis and treatment as well as potentially egregious or unnecessary diagnostic or therapeutic actions, was obtained. The raters were instructed to make a mark on a 10-cm horizontal line based on their assessment of the trainee's performance. The global rating system was anchored by the lowest value 0 (unsatisfactory) and the highest value 10 (outstanding).

Analysis. From a generalizability standpoint, the G study described above was fully crossed ($p \times t \times r$). All of the raters ($n_r = 3$) provided a score for each of the six ($n_t = 6$) scenarios (referred to as tasks) across all 28 trainees (objects of measurement). The person by rater by task design can be used to investigate the sources of measurement error in the simulation scores. Here, it was expected that the principle source of variance in scores would be associated with differences in individual resident's abilities, not choice of task or choice rater.

Generalizability (G) Study. The analysis of G study, including the provision of estimated variance components, could be done by hand. There are, however, a number of available software packages that

4 Generalizability Theory: Basics

Table 1 Estimated variance components, standard errors of measurements, generalizability, and dependability coefficients for simulation scores (G and D studies)

G Study		D studies – mean variance component			
Component	Estimate ^a	Component	t = 6, r = 3	t = 6, r = 2	t = 8, r = 2
Person ($\hat{\sigma}_p^2$)	1.28	Person ($\hat{\sigma}_p^2$)	1.28	1.28	1.28
Task ($\hat{\sigma}_t^2$)	0.51	Task ($\hat{\sigma}_t^2$)	0.09	0.09	0.06

		$E\rho^2$	0.72	0.68	0.73

^aestimate for single person by task by rater combinations.

make this task much less cumbersome [4, 5, 9]. In addition, commonly used statistical programs typically have routines for estimating variance components for a multitude of G study designs. For this example, the SAS PROC VARCOMP routine was used [16].

The estimated variance components for the G study are presented in Table 1. The person (trainee) variance component ($\hat{\sigma}^2(p)$) is an estimate of the variance across trainees of trainee-level mean scores. If one could obtain the person's expected score over all tasks and raters in the universe of admissible observations, the variance of these scores would be $\hat{\sigma}^2(p)$. Ideally, most of the variance should be here, indicating that individual abilities account for differences in observed scores. The other "main effect" variance components include task ($\hat{\sigma}^2(t)$) and rater ($\hat{\sigma}^2(r)$). The task component is the estimated variance of scenario mean scores. Since the estimate is greater than zero, we know that the six tasks vary somewhat in average difficulty. Not surprisingly, mean performance, by simulation scenario, ranged from a low of 5.7 to a high of 8.2. The rater component is the variance of the rater mean scores. The nonzero value indicates that raters vary somewhat in terms of average stringency. The mean rater scores, on a scale from 0 to 10, were 7.4, 6.3, and 7.0, respectively. Interestingly, the task variance component is approximately twice as large as the rater component. We can, therefore, conclude that raters differ much less

in average stringency than simulation scenarios differ in average difficulty.

The largest interaction variance component was person by task ($\hat{\sigma}^2(pt)$). The magnitude of this component suggests that there are considerably different rank orderings of examinee mean scores for each of the various simulation scenarios. The relatively small person by rater component suggests that the various raters rank order persons similarly. Likewise, the small rater by task component indicates that the raters rank order the difficulty of the simulation scenarios similarly. The final variance component is the residual variance that includes the triple-order interactions and all other unexplained sources of variation.

Decision (D) Studies. The G study noted above was used to derive estimates of variance components associated with a universe of admissible observations. Decision (D) studies can use these estimates to design efficient measurement procedures for future operations. To do this, one must specify universe of generalization. For the simulation assessment, we may want to generalize trainees' scores based on the six tasks and three raters to trainees' scores for a universe of generalization that includes many other tasks and many other raters. In this instance, the universe of generalization is "infinite" in that we wish to generalize to any set of raters and any set of tasks. Here, consistent with ANOVA terminology, both the rater and task facets are said to be random as opposed to fixed.

For the simulation assessment, we may decide that we want each trainee to be assessed in each of the six encounters (tasks; $n'_t = 6$) and each of the tasks be rated by three independent raters ($n'_r = 3$). Although the sample sizes for the D study are the same as those for the G study, this need not be the case. Unlike the G study, which focused on single trainee by task by rater observations, the D study focuses on mean scores for persons.

The D study variance components can be easily estimated using the G study variance components in Table 1 (see Table 1). The estimated random effects variance components are for person mean scores over $n'_t = 6$ tasks and $n'_r = 3$ raters. The calculation of the variance components for this fully crossed design is relatively straightforward. The estimated universe score variance ($\hat{\sigma}_p^2$) stays the same. To obtain means, variance components that contain t but not r are divided by n'_t . Components that contain r but not t are divided by n'_r . And components that contain both t and r are divided by $n'_t n'_r$.

Since an infinite universe of generalization has been defined, all variance components other than $\hat{\sigma}^2(p)$ contribute to one or more types of error variance. If the trainee scores are going to be used for mastery decisions (e.g., pass/fail), then all sources of error are important. Here, both simulation scenario difficulty and rater stringency are potential sources of error in estimating "true" ability. Absolute error is simply the difference between a trainee's observed and universe score. Variance of the absolute errors $\sigma^2(\Delta)$ is the sum of all variance components except $\sigma^2(p)$ (see Table 1). The square root of this value $\hat{\sigma}(\Delta)$ is interpretable as the absolute standard error of measurement (SEM). On the basis of the D study described above, $\hat{\sigma}(\Delta) = 0.83$. As a result, $X_{pTR} \pm 1.62$ constitutes an approximate 95% confidence interval for trainees' universe scores.

If the purpose of the simulation assessment is simply to rank order the trainees, then some component variances will not contribute to error. For these measurement situations, relative error variance $\hat{\sigma}^2(\delta)$ similar to error variance in CTT is central. For the $p \times T \times R$ D study with $n'_t = 6$ and $n'_r = 3$ relative error variance is the sum of all variance components, excluding $\sigma^2(p)$, that contain p (i.e., $\hat{\sigma}_{pT}^2, \hat{\sigma}_{pR}^2, \hat{\sigma}_{pTR}^2$). These are the only sources of variance that can impact the relative ordering of trainee scores. The calculated value ($\hat{\sigma}^2(\delta) = 0.51$) is necessarily lower than $\hat{\sigma}^2(\Delta)$, in that fewer variance components are

considered. The square root of the relative error variance ($\hat{\sigma}(\delta) = 0.71$) is interpretable as an estimate of the relative SEM. As would be expected, and borne out by the data, absolute interpretations of a trainee's score are more error-prone than relative ones.

In addition to calculating error variances, two types of reliability-like coefficients are widely used in generalizability theory. The generalizability coefficient ($E\rho^2$), analogous to a reliability coefficient in CTT, is the ratio of universe score variance to itself plus error variance:

$$E\rho^2 = \frac{\sigma^2(p)}{\sigma^2(p) + \sigma^2(\delta)}. \quad (3)$$

For $n'_t = 6$ and $n'_r = 3$, $E\rho^2 = 0.72$. An index of dependability (Φ) can also be calculated:

$$\Phi = \frac{\sigma^2(p)}{\sigma^2(p) + \sigma^2(\Delta)}. \quad (4)$$

This is the ratio of universe score variance to itself plus absolute score variance. For $n'_t = 6$ and $n'_r = 3$, $\Phi = 0.65$. The dependability coefficient is apropos when absolute decisions about scores are being made. For example, if the simulation scores, in conjunction with a defined standard, were going to be used for licensure or certification decisions, then all potential error sources are important, including those associated with variability in task difficulty and rater stringency.

The $p \times T \times R$ design with two random facets (tasks, $n'_t = 6$; raters, $n'_r = 3$) was used for illustrative purposes. However, based on the relative magnitudes of the G study variance components, it is clear that the reliability of the simulation scores is generally more dependent on the number of simulation scenarios as opposed to the number of raters. One could easily model a different D study design and calculate mean variance components for $n'_t = 6$ and $n'_r = 2$ (see Table 1). By keeping the same number of simulated encounters, and decreasing the number of raters per case ($n'_r = 2$), the overall generalizability and dependability coefficients are only slightly lower. Increasing the number of tasks ($n'_t = 8$) while decreasing the number of raters per task ($n'_r = 2$) has the effect of lowering both absolute and relative error variance. Ignoring the specific costs associated with developing simulation exercises, testing trainees, and rating performances, increasing the number of tasks, as opposed to raters per given task, would appear to

be the most efficient means of enhancing the precision of examinee scores.

Fixed Facets. The D studies described above ($p \times T \times R$) involved two random facets and a universe of generalization that was infinite. Here, we were attempting to generalize to any other set of simulation exercises and any other group of raters. This does not, however, always have to be the case. If we were only interested in generalizing to the six simulation scenarios that were initially modeled, but some set of randomly selected raters, then a mixed model results. The task facet is said to be fixed, as opposed to random, and the universe of generalization is thereby restricted. In essence, we are considering the six simulation scenarios to be the universe of all simulation scenarios. On the basis of the fully crossed $p \times t \times r$ G study design, the variance components for a design with a fixed T can be calculated quite easily. For D study sample sizes ($n'_t = 6$ and $n'_r = 3$), with T fixed, the generalizability coefficient $E\rho^2$ is estimated to be 0.91. Although this value is much larger than that estimated for a design with a random task facet ($E\rho^2 = 0.72$), one cannot generalize to situations in which other simulation exercises are used.

Nested Designs. The G study employed a fully crossed $p \times t \times r$ design with an infinite universe of admissible observations. Here, all tasks (simulation scenarios) were evaluated by all raters. Given that the cost of physician raters is high and the G study variance components associated with the rater were comparatively low, one could also envision a situation where there were multiple tasks but only a single (different) rater for each performance. This describes a nested design ($p \times (R:T)$), where R:T denotes rater nested in task. For a design with $n'_t = 6$ and $n'_r = 1$, the random effects D study variance components, including $\hat{\sigma}^2(R:T)$ and $\hat{\sigma}^2(pR:T)$, can be calculated from the appropriate G study variance components. For the simulation study, the estimated values of Φ and $E\rho^2$ would be 0.64 and 0.69, respectively. Interestingly, these values are only slightly lower than those for a random model with $n'_t = 6$ and $n'_r = 3$ raters (per task). From a measurement perspective, this suggests that a design involving multiple tasks and a single rater per task would be comparatively efficient.

Conclusion

From a descriptive point of view, generalizability theory involves the application of ANOVA techniques to measurement procedures. Its major contribution is that it permits the decision-maker to pinpoint sources of measurement error and change the appropriate number of observations accordingly in order to obtain a certain level of generalizability. Unlike CTT, which considers a single source of error (E), generalizability theory allows for multiple sources of error, permits direct comparison of these error sources, allows for different 'true' (universe) scores, and provides an analysis framework for determining optimal measurement conditions to attain desired precision.

Generalizability theory has been applied to many real-world measurement problems, including standard setting and equating exercises [11, 13], computerized scoring applications [8], and the design of various performance-based assessments [7]. There have also been numerous advances in generalizability theory, including work related to model fit and estimation methods [6], sampling issues [14], and applications of multivariate specifications [12].

Generalizability Theory: Estimation

Introduction

Generalizability theory (G theory) is a conceptual and statistical framework for the analysis and construction of measurement instruments. The first extensive treatment of G theory was presented by Cronbach, Gleser, Nanda, and Rajaratnam [3] and the most recent one by Brennan [2]. Less extensive introductions to G theory can be found in publications by Shavelson and Webb [6] and Brennan [1].

In most testing situations, it is not the particular sample of items or the particular sample of raters involved in an evaluation of a person's performance that is of interest. Different samples of items and different samples of raters would be equally acceptable or admissible. All the admissible items and raters together constitute the universe of admissible observations, which we would ideally like to administer to determine a person's universe score. This being unfeasible, we have to work with the person's performance on a particular sample of items evaluated by a particular sample of raters, that is, the person's observed score. The question is to what extent can we generalize from observed score to universe score. In G theory, the answer to this generalizability question is quantified by generalizability coefficients.

Conceptual Framework of G Theory

In G theory, behavioral measurements or observations are described in terms of conditions; a set of similar conditions is referred to as a *facet*. An achievement test with 40 multiple-choice items is said to have 40 conditions of the facet 'items'; a performance test with 10 tasks evaluated by two raters has 10 conditions of the facet 'tasks' and 2 conditions of the facet 'raters.' The objects being measured, usually persons, are not regarded as a facet.

Responses are obtained by means of designs where objects of measurement have to respond to the conditions of one or more facets. Designs differ not only in the number of facets (one or more) and the nature of the facets (random or fixed) but also

in how the conditions of the facet are administered (crossed or nested). The term-crossed design means that the persons have to respond to all the conditions of all the facets; with a nested design, they have to respond to only a selection of the conditions of the facets.

One-facet Design

In a one-facet crossed design, the observed score for one person on one item, X_{pi} , can be decomposed as

$$\begin{aligned} X_{pi} &= \mu && \text{(grand mean)} \\ &+ \mu_p - \mu && \text{(person effect)} \\ &+ \mu_i - \mu && \text{(item effect)} \\ &+ X_{pi} - \mu_p - \mu_i + \mu && \text{(residual effect)} \end{aligned} \quad (1)$$

The model in (1) has three parameters. The first parameter, the grand mean or the mean over the population of persons and the universe of items, is defined as $\mu \equiv \varepsilon_p \varepsilon_i X_{pi}$. The second parameter, the universe score of a person or the mean score over the universe of items, is defined as $\mu_p \equiv \varepsilon_i X_{pi}$. The third parameter, the population mean of an item or the mean score over the population of persons, is defined as $\mu_i \equiv \varepsilon_p X_{pi}$. Except for the grand mean, the three effects in (1) have a distribution with a mean of zero and a positive variance. For example, the mean of the person effect is $\varepsilon_p(\mu_p - \mu) = \varepsilon_p(\mu_p) - \varepsilon_p(\mu) = \mu - \mu = 0$. Each effect or component has its own variance component. The **variance components** for persons, items, and the residual or error are defined as $\sigma_p^2 = \varepsilon_p(\mu_p - \mu)^2$, $\sigma_i^2 = \varepsilon_i(\mu_i - \mu)^2$, and $\sigma_{pi,e}^2 = \varepsilon_p \varepsilon_i (X_{pi} - \mu_p - \mu_i + \mu)^2$. The variance of the observed scores is defined as $\sigma_X^2 = \sigma^2(X_{pi}) = \varepsilon_p \sigma_i^2 (X_{pi} - \mu)^2$. It can be shown that σ_X^2 , the total variance, is equal to the sum of the three variance components: $\sigma_X^2 = \sigma_p^2 + \sigma_i^2 + \sigma_{pi,e}^2$.

Generalizability and Decision Study

In generalizability theory, a distinction is made between a generalizability study (G study) and a decision study (D study). In a G study, the variance components are estimated using procedures from analysis of variance. In a D study, these variance components are used to make decisions on, for example, how many items should be included in the test or how

2 Generalizability Theory: Estimation

many raters should evaluate the responses. A G study of a one-facet crossed random effects design is presented below. A D study of this design is discussed in the next section.

Generalizability Study One-facet Design

The **Analysis of Variance** table of a crossed one-facet random effects design, a design where a random sample of n_p persons from a population of persons responds to a random sample of n_i items from a universe of items, is presented in Table 1.

From Table 1, we can see that we first have to compute the sums of squares in order to estimate the variance components. For that, we substitute the three parameters μ , μ_p , and μ_i in (1) with their observed counterparts, which results in the following decomposition:

$$\begin{aligned} X_{pi} &= \bar{X} + (\bar{X}_p - \bar{X}) + (\bar{X}_i - \bar{X}) \\ &\quad + (X_{pi} - \bar{X}_p - \bar{X}_i + \bar{X}) \\ &= X_{pi} - \bar{X} = (\bar{X}_p - \bar{X}) + (\bar{X}_i - \bar{X}) \\ &\quad + (X_{pi} - \bar{X}_p - \bar{X}_i + \bar{X}) \end{aligned} \quad (2)$$

By squaring and summing the observed deviation scores in (2), four sums of squares are obtained: the total sums of squares and the sums

of squares of persons, items, and interactions. The total sums of squares, $\sum_p \sum_i (X_{pi} - \bar{X})^2$, is equal to the sum of the three other sums of squares: $\sum_p \sum_i (X_p - \bar{X})^2 + \sum_p \sum_i (X_i - \bar{X})^2 + \sum_p \sum_i (X_{pi} - \bar{X}_p - \bar{X}_i + \bar{X})^2$. The former is also written as $SS_{\text{tot}} = SS_p + SS_i + SS_{pi,e}$. The mean squares can be computed from the sums of squares. Solving the equations of the expected mean squares for the variance components and replacing the observed mean squares by their expected values results in the following estimators for the variance components: $\hat{\sigma}_p^2 = (MS_p - MS_{pi,e})/n_i$, $\hat{\sigma}_i^2 = (MS_i - MS_{pi,e})/n_p$, and $MS_{pi,e} = \hat{\sigma}_{pi,e}^2$.

The artificial example in Table 2 was used to obtain the G study results presented in Table 3.

Table 2 contains the scores (0 or 1) of four persons on three items, the mean scores of the persons, the mean scores of the items, and the general mean. The mean scores of the persons vary between a perfect mean score of 1 and a mean score of 0. The mean scores of the items range from an easy item of 0.75 to a difficult item of 0.25.

The last column of Table 3 contains the estimated variance components which are variance components of scores of single persons on single items. Since the size of the components depends on the score scale of the items, the absolute size of the variance components does not yield very useful information.

Table 1 Analysis of variance table of a crossed one-facet random effects design

Effects	Sums of squares	Degrees of freedom	Mean squares	Expected mean squares
Persons (p)	SS_p	$df_p = n_p - 1$	$MS_p = SS_p/df_p$	$\Sigma(MS_p) = \sigma_{pi,e}^2 + n_i \sigma_p^2$
Items (i)	SS_i	$df_i = n_i - 1$	$MS_i = SS_i/df_i$	$\Sigma(MS_i) = \sigma_{pi,e}^2 + n_p \sigma_i^2$
Residual (pi, e)	$SS_{pi,e}$	$df_{pi,e} = (n_p - 1) \times (n_i - 1)$	$MS_{pi,e} = SS_{pi,e}/df_{pi,e}$	$\Sigma(MS_{pi,e}) = \sigma_{pi,e}^2$

Table 2 The item scores of four persons on three items, the mean score per person and per item, and the general mean

Person	Item			$\bar{X}_p$
	1	2	3	
1	1	1	1	1.000
2	1	1	0	0.667
3	1	0	0	0.333
4	0	0	0	0.000
$\bar{X}_i$	0.75	0.50	0.25	0.500 = $\bar{X}$

Table 3 Results generalizability study for the example from Table 2

Effects	Sums of squares	Degrees of freedom	Mean squares	Estimates of variance components
Persons (p)	1.667	3	0.556	$\hat{\sigma}_p^2 = 0.139$ (45.5%)
Items (i)	0.500	2	0.250	$\hat{\sigma}_i^2 = 0.028$ (9%)
Residual (pi, e)	0.833	6	0.139	$\hat{\sigma}_{pi,e}^2 = 0.139$ (45.5%)

It is therefore common practice to report the size of the component as a percentage of the total variance. Since the items are scored on a 0 to 1 score scale, the variance component cannot be larger than 0.25. The reason for the large universe score variance is the large differences between the mean scores of the four persons. The estimated variance component for the items is relatively small. This can be confirmed by taking the square root of the variance components, resulting in a standard deviation of 0.17, which is approximately one-sixth of the range for items scored on a dichotomous score scale. This value is what we might expect under a normal distribution of the scores.

Decision Study One-facet Design

The model in (1) and its associated variance components relate to scores of single persons on single items from the universe of admissible observations. However, the evaluation of a person's performance is never based on the score obtained on a single item, but on a test with a number of items. What the effect is of increasing the number of items on the variance components was investigated in a D study.

The linear model for the decomposition of the mean score of a person on a test with n_i items, denoted by X_{pI} , is

$$X_{pI} = \mu + (\mu_p - \mu) + (\mu_I - \mu) + (X_{pI} - \mu_p - \mu_I + \mu). \quad (3)$$

In (3), the symbol I is used to indicate the mean score on a number of items. In (3), the universe score is defined as $\mu_p \equiv \Sigma_I X_{pI}$, the expected value of X_{pI} over random parallel tests. By taking the expectation over I in (3), the universe score variance σ_p^2 does not change; the two other variance components do change and are defined as $\sigma_I^2 = \sigma_i^2/n_i'$ and $\sigma_{pi,e}^2 = \sigma_{pi,e}^2/n_i'$. The total variance, $\sigma_X^2 = \sigma^2(X_{pI})$, is equal to $\sigma_X^2 = \sigma_p^2 + \sigma_I^2 + \sigma_{pi,e}^2$.

Table 4 contains the variance components from the G study and the D study with three items.

The results in Table 4 show how the variance component of the items and the variance component of the interaction or error component change if we increase the number of items. To gauge the effect of using three more items from the universe of admissible observations, we have to divide the appropriate G-study variance components by 6.

The purpose of many tests is to determine the position of a person in relation to other persons. In generalizability theory, the relative position of a person is called the *relative universe score* and defined as $\mu_p - \mu$. The relative universe score is estimated by $X_{pI} - X_{PI}$, the difference between the mean test score of a person and the mean test score of the sample of persons. The deviation between $X_{pI} - X_{PI}$ and $\mu_p - \mu$ is called *relative error* and is defined as $\delta_{pI} = (X_{pI} - X_{PI}) - (\mu_p - \mu)$. The estimated relative error variance is equal to $\hat{\sigma}_\delta^2 = \hat{\sigma}_{pi,e}^2$. (Note that the prime is used to indicate the sample sizes in a D study.) For the crossed one-facet random effects design, the estimate of the

Table 4 Results of G study and D study for the example from Table 2

Effects	Variance components G study	Variance components D study
Persons (p)	$\hat{\sigma}_p^2 = 0.139$	$\hat{\sigma}_p^2 = 0.139$
Items (i)	$\hat{\sigma}_i^2 = 0.028$	$\hat{\sigma}_i^2 = 0.028/3 = 0.009$
Residual (pi, e)	$\hat{\sigma}_{pi,e}^2 = 0.139$	$\hat{\sigma}_{pi,e}^2 = 0.139/3 = 0.046$

4 Generalizability Theory: Estimation

generalizability coefficient for relative decisions, $\hat{\rho}^2$, is defined as

$$\hat{\rho}^2 = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \hat{\sigma}_\delta^2}.$$

Table 4 shows that the universe score variance for the test with three items is equal to 0.139 and the relative error variance is equal to 0.046. The generalizability coefficient, which has a lower limit of 0 and an upper limit of 1, is equal to 0.75. There are two possible interpretations of this coefficient. The first is that the coefficient is approximately equal to the expected value of the squared correlation between observed and universe score. The second is that the coefficient is approximately equal to the correlation between pairs of two randomly parallel tests.

It can be shown [4] that $\hat{\rho}^2$ is equal to the reliability coefficient KR-20 for dichotomous item scores and equal to Cronbach's coefficient alpha for polytomous scores. In addition to the reliability and generalizability coefficient, the standard error of measurement is also used as an indicator for the reliability of measurement instruments. The relative standard error of measurement is obtained by taking the square root of the relative error variance and can be shown to be equal to the standard error of measurement from classical test theory.

The purpose of a measurement instrument can also be to determine a person's absolute universe score. For example, if we want to know that a person can give a correct answer to at least 80% of the test items. The absolute universe score, μ_p , is estimated by X_{pI} . The deviation between X_{pI} and μ_p is called *absolute error* and is defined as $\Delta_{pI} = X_{pI} - \mu_p = (\mu_I - \mu) + (X_{pI} - \mu_p - \mu_I + \mu)$. The estimated absolute error variance is equal to $\hat{\sigma}_\Delta^2 = \hat{\sigma}_I^2 + \hat{\sigma}_{pI,e}^2$. For a crossed one-facet random effects design, the estimate of the generalizability coefficient, $\hat{\phi}$, for absolute decisions is defined as

$$\hat{\phi} = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \hat{\sigma}_\Delta^2}.$$

For the example in Table 2 with three items, the generalizability coefficient for absolute decisions is equal to 0.72.

Two-facet Design

In a crossed two-facet design, the observed score of person p on item i awarded by rater r , X_{pir} , can be

decomposed into seven components:

$$\begin{aligned} X_{pir} &= \mu && \text{(grand mean)} \\ + \mu_p - \mu &&& \text{(person effect)} \\ + \mu_i - \mu &&& \text{(item effect)} \\ + \mu_r - \mu &&& \text{(rater effect)} \\ + \mu_{pi} - \mu_p - \mu_i + \mu &&& \text{(person} \times \text{item effect)} \\ + \mu_{pr} - \mu_p - \mu_r + \mu &&& \text{(person} \times \text{rater effect)} \\ + \mu_{ir} - \mu_i - \mu_r + \mu &&& \text{(item} \times \text{rater effect)} \\ + X_{pir} - \mu_{pi} - \mu_{pr} &&& \\ - \mu_{ir} + \mu_p + \mu_i &&& \\ + \mu_r - \mu &&& \text{(residual effect)} \end{aligned} \quad (4)$$

The seven parameters in (4) are defined as $\mu \equiv \varepsilon_p \varepsilon_i \varepsilon_r X_{pir}$, $\mu_p \equiv \varepsilon_i \varepsilon_r X_{pir}$, $\mu_i \equiv \varepsilon_p \varepsilon_r X_{pir}$, $\mu_r \equiv \varepsilon_p \varepsilon_i X_{pir}$, $\mu_{pi} \equiv \varepsilon_r X_{pir}$, $\mu_{pr} \equiv \varepsilon_i X_{pir}$, and $\mu_{ir} \equiv \varepsilon_p X_{pir}$.

A crossed two-facet design has a total of seven variance components. The total variance is equal to $\sigma_X^2 = \sigma_p^2 + \sigma_i^2 + \sigma_r^2 + \sigma_{pi}^2 + \sigma_{pr}^2 + \sigma_{ir}^2 + \sigma_{pir,e}^2$. Estimates of variance components can be obtained using procedures comparable to the one described for the crossed one-facet design.

Generalizability Study Two-facet Design

Table 5 contains an example, taken from Thorndike [7], of a crossed two-facet design where two raters have awarded a score to the answers on four items of six persons.

The results of the generalizability study for the example in Table 5 are presented in Table 6.

The last column in Table 6 contains the estimates of the variance components and the contribution of each component to the total variance in terms of percentage. In this example, the variance component for raters is negative. Negative estimates can result from using the wrong model or too small a sample. It should be noted that standard errors of variance components with small numbers of persons and conditions are very large. To obtain acceptable standard errors according to Smith [8], the sample should be at least a hundred persons. There are different approaches to dealing with negative estimates. One of them is to set the negative estimates to zero. The relatively large contribution of the variance component of items can be ascribed to the large differences between the mean scores of the items. The contribution of the interaction component between persons

Table 5 The item scores of six persons on four items and two raters, per rater the mean score per item and per person, the mean score per rater, the mean score per person, and the general mean

Pers.	Rater 1					$\bar{X}_{p1}$	Rater 2					$\bar{X}_{p2}$	$\bar{X}_p$

Table 6 Results of the generalizability study for example from Table 5

Effects	Sums of squares	Degrees of freedom	Mean squares	Estimates of variance components
Persons (p)	109.75	5	21.95	$\hat{\sigma}_p^2 = 2.16$ (28%)
Items (i)	85.17	3	28.39	$\hat{\sigma}_i^2 = 1.26$ (15%)
Raters (r)	8.33	1	8.33	$\hat{\sigma}_r^2 = -0.15$ (0%)
Persons $\times$ Items (pi)	59.08	15	3.94	$\hat{\sigma}_{pi}^2 = 0.99$ (12%)
Persons $\times$ Raters (pr)	13.42	5	2.68	$\hat{\sigma}_{pr}^2 = 0.18$ (2%)
Items $\times$ Raters (ir)	33.83	3	11.28	$\hat{\sigma}_{ir}^2 = 1.55$ (19%)
Residual (pir, e)	29.42	15	1.96	$\hat{\sigma}_{pir,e}^2 = 1.96$ (24%)

and items is much larger than the interaction component between persons and raters. Interaction between persons and items means that persons do not give consistent reactions to different questions with the result that depending on the question the relative position of the persons differs.

Decision Study Two-facet Design

The linear model for the decomposition of the average score of a person on a test with n_i items of which the answers were rated by n_r raters, denoted by X_{pIR} , is

$$\begin{aligned}
 X_{pIR} = & \mu + (\mu_p - \mu) + (\mu_I - \mu) + (\mu_R - \mu) \\
 & + (\mu_{pI} - \mu_p - \mu_I + \mu) \\
 & + (\mu_{pR} - \mu_p - \mu_R + \mu) \\
 & + (\mu_{IR} - \mu_I - \mu_R + \mu) \\
 & + (X_{pIR} - \mu_{pI} - \mu_{pR} - \mu_{IR} \\
 & + \mu_p + \mu_I + \mu_R - \mu).
 \end{aligned}$$

The seven variance components associated with this model are $\sigma_p^2, \sigma_I^2 = \sigma_i^2/n_i', \sigma_R^2 = \sigma_r^2/n_r', \sigma_{pI}^2 = \sigma_{pi}^2/n_i', \sigma_{pR}^2 = \sigma_{pr}^2/n_r', \sigma_{IR}^2 = \sigma_{ir}^2/n_i'n_r', \sigma_{pIR,e}^2 = \sigma_{pir,e}^2/n_i'n_r'$.

The total variance is equal to $\sigma_X^2 = \sigma_p^2 + \sigma_I^2 + \sigma_R^2 + \sigma_{pI}^2 + \sigma_{pR}^2 + \sigma_{IR}^2 + \sigma_{pIR,e}^2$.

The estimate of the generalizability coefficient for relative decisions for the crossed two-facet random effects design is defined as

$$\hat{\rho}^2 = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \frac{\hat{\sigma}_{pi}^2}{n_i'} + \frac{\hat{\sigma}_{pr}^2}{n_r'} + \frac{\hat{\sigma}_{pir,e}^2}{n_i'n_r'}}.$$

The denominator of this coefficient has three variance components that relate to interactions with persons. Interaction between persons and items means that on certain items a person performs better than other persons, while on certain other items the performance is worse. This inconsistent performance by persons on items contributes to error variance. Interaction between persons and raters

means that a person is awarded different scores by different raters. This inconsistent rating by raters contributes to error variance. The residual variance component is by definition error variance and the interaction component between persons, items, and raters.

For the example in Table 5, with four items and two raters, the generalizability coefficient is equal to $2.16/(2.16 + 0.99/4 + 0.18/2 + 1.96/8) = 0.79$. This generalizability coefficient can be improved by increasing the number of observations, that is, the product of the number of items and the number of raters. Having more items, however, will have a much greater effect than more raters because the variance component of the interaction between persons and items is much larger than the variance component of the interaction between persons and raters. This example shows that the Spearman–Brown formula from classical theory does not apply to multifacet designs from generalizability theory. Procedures for selecting the optimal number of conditions in multifacet designs have been presented by Sanders, Theunissen, and Baas [5].

The estimate of the generalizability coefficient for absolute decisions for the crossed two-facet random effects design is defined as

$$\hat{\phi} = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \frac{\hat{\sigma}_i^2}{n'_i} + \frac{\hat{\sigma}_r^2}{n'_r} + \frac{\hat{\sigma}_{pi}^2}{n'_i} + \frac{\hat{\sigma}_{pr}^2}{n'_r} + \frac{\hat{\sigma}_{ir}^2}{n'_i n'_r} + \frac{\hat{\sigma}_{pir,e}^2}{n'_i n'_r}}.$$

For making absolute decisions, it does matter whether we administer a test with difficult items or a test with easy items or have the answers rated by lenient or strict raters. Therefore, the variance components of the items and the raters, and the variance component of the interaction between items and raters also contribute to the error variance. For the example in Table 5, the generalizability coefficient for absolute decisions is equal to $2.16/(2.16 + 1.26/4 + 0.0/2 + 0.99/4 + 0.18/2 + 1.55/8 + 1.96/8) = 0.66$.

Other Designs

In the previous sections, it was shown that modifying the number of items and/or raters could affect the generalizability coefficient. However, the generalizability coefficient can also be affected by changing

the universe to which we want to generalize. We can, for example, change the universe by interpreting a random facet as a fixed facet. If the items in the example with four items and two raters are to be interpreted as a fixed facet, only these four items are admissible. If the facet ‘items’ is interpreted as a fixed facet, generalization is no longer to the universe of random parallel tests with four items and two raters, but to the universe of random parallel tests with two raters. Interpreting a random effect as a fixed facet means that fewer variance components can be estimated. In a crossed two-facet mixed effects design, the three variance components that can be estimated, expressed in terms of the variance components of the crossed two-facet random effects design, are $\hat{\sigma}_{p*}^2 = \hat{\sigma}_p^2 + \hat{\sigma}_{pi}^2/n'_i$, $\hat{\sigma}_{r*}^2 = \hat{\sigma}_r^2 + \hat{\sigma}_{ir}^2/n'_i$, and $\hat{\sigma}_{pr,e*}^2 = \hat{\sigma}_{pr}^2 + \hat{\sigma}_{pir,e}^2/n'_i$. The estimate of the generalizability coefficient for relative decisions for the crossed two-facet mixed effects design, originally derived by Maxwell and Pilliner [4], is defined as

$$\begin{aligned} \hat{\rho}^2 &= \frac{\hat{\sigma}_{p*}^2}{\hat{\sigma}_{p*}^2 + \hat{\sigma}_{pr,e*}^2/n'_r} \\ &= \frac{\hat{\sigma}_p^2 + \hat{\sigma}_{pi}^2/n'_i}{\hat{\sigma}_p^2 + \hat{\sigma}_{pi}^2/n'_i + \hat{\sigma}_{pr}^2/n'_r + \hat{\sigma}_{pir,e}^2/n'_i n'_r}. \end{aligned}$$

With the facet ‘items’ fixed, the generalizability coefficient for our example is equal to 0.88, compared to a generalizability coefficient of 0.79 with the facet ‘items’ being random. This increase of the coefficient is expected since, by restricting the universe, the relative decisions about persons will be more accurate.

In G theory, nested designs can also be analyzed. Our example with two facets would be a nested design if the first two questions were evaluated by the first rater and the other two questions by the second rater. In a design where raters are nested within questions, the variance component of raters and the variance component of the interaction between persons and raters cannot be estimated. The estimate of the generalizability coefficient for relative decisions for the nested two-facet random effects design is defined as

$$\hat{\rho}^2 = \frac{\hat{\sigma}_p^2}{\hat{\sigma}_p^2 + \frac{\hat{\sigma}_{pi}^2}{n'_i} + \frac{\hat{\sigma}_{pr,pir,e}^2}{n'_i n'_r}}.$$

The estimates of variance components of the crossed two-facet random effects design can be used to estimate the variance components of not only a nested two-facet random effects design but also those of a nested two-facet mixed effects design. Because of their versatility, crossed designs should be given preference.

G theory is not limited to the analysis of univariate models; multivariate models where persons have more than one universe score can also be analyzed. In G theory, persons as well as facets can be selected as objects of measurement, making G theory a conceptual and statistical framework for a wide range of research problems from different disciplines.

Generalizability Theory: Overview

Generalizability (G) theory is a statistical theory for evaluating the dependability ('reliability') of behavioral measurements [2]; see also [1], [3], and [4]. G theory pinpoints the sources of measurement error, disentangles them, and estimates each one. In G theory, a behavioral measurement (e.g., a test score) is conceived of as a sample from a *universe of admissible observations*, which consists of all possible observations that decision makers consider to be acceptable substitutes for the observation in hand. Each characteristic of the measurement situation that a decision maker would be indifferent to (e.g., test form, item, occasion, rater) is a potential source of error and is called a *facet of a measurement*. The universe of admissible observations, then, is defined by all possible combinations of the levels (called *conditions*) of the facets. In order to evaluate the dependability of behavioral measurements, a *generalizability (G) study* is designed to isolate and estimate as many facets of measurement error as is reasonably and economically feasible.

Consider a two-facet crossed person $\times$ item $\times$ occasion G study design where items and occasions have been randomly selected. The *object of measurement*, here persons, is not a source of error and, therefore, is not a facet. In this design with generalization over all admissible test items and occasions taken from an indefinitely large universe, an observed score for a particular person on a particular item and occasion is decomposed into an effect for the grand mean, plus effects for the person, the item, the occasion, each two-way interaction (see **Interaction Effects**), and a residual (three-way interaction plus unsystematic error). The distribution of each component or 'effect', except for the grand mean, has a mean of zero and a variance σ^2 (called the **variance component**). The variance component for the person effect is called the *universe-score variance*. The variance components for the other effects are considered error variation. Each variance component can be estimated from a traditional **analysis of variance** (or other methods such as **maximum likelihood**). The relative magnitudes of the estimated variance components provide information about sources of error influencing a behavioral measurement. Statistical tests are not

used in G theory; instead, standard errors for variance component estimates provide information about sampling variability of estimated variance components.

The *decision (D) study* deals with the practical application of a measurement procedure. A D study uses variance component information from a G study to design a measurement procedure that minimizes error for a particular purpose. In planning a D study, the decision maker defines the universe that he or she wishes to generalize to, called the *universe of generalization*, which may contain some or all of the facets and their levels in the universe of admissible observations. In the D study, decisions usually will be based on the mean over multiple observations (e.g., test items) rather than on a single observation (a single item).

G theory recognizes that the decision maker might want to make two types of decisions based on a behavioral measurement: relative ('norm-referenced') and absolute ('criterion- or domain-referenced'). A *relative decision* focuses on the rank order of persons; an *absolute decision* focuses on the level of performance, regardless of rank. Error variance is defined differently for each kind of decision. To reduce error variance, the number of conditions of the facets may be increased in a manner analogous to the Spearman–Brown prophecy formula in classical test theory and the standard error of the mean in sampling theory. G theory distinguishes between two reliability-like summary coefficients: a Generalizability (G) Coefficient for relative decisions and an Index of Dependability (Phi) for absolute decisions.

Generalizability theory allows the decision maker to use different designs in G and D studies. Although G studies should use crossed designs whenever possible to estimate all possible variance components in the universe of admissible observations, D studies may use nested designs for convenience or to increase estimated generalizability.

G theory is essentially a random effects theory. Typically, a random facet is created by randomly sampling levels of a facet. A fixed facet arises when the decision maker: (a) purposely selects certain conditions and is not interested in generalizing beyond them, (b) finds it unreasonable to generalize beyond the levels observed, or (c) when the entire universe of levels is small and all levels are included in the measurement design (see **Fixed and Random Effects**). G theory typically treats fixed facets by averaging over the conditions of the fixed facet and examining

2 Generalizability Theory: Overview

the generalizability of the average over the random facets. Alternatives include conducting a separate G study within each condition of the fixed facet, or a multivariate analysis with the levels of the fixed facet comprising a vector of dependent variables.

As an example, consider a G study in which persons responded to 10 randomly selected science items on each of 2 randomly sampled occasions. Table 1 gives the estimated variance components from the G study. The large $\hat{\sigma}_p^2$ (1.376, 32% of the total variation) shows that, averaging over items and occasions, persons in the sample differed systematically in their science achievement. The other estimated variance components constitute error variation; they concern the item facet more than the occasion facet. The non-negligible $\hat{\sigma}_i^2$ (5% of total variation) shows that items varied somewhat in difficulty level. The large $\hat{\sigma}_{pi}^2$ (20%) reflects different relative standings of persons across items. The small $\hat{\sigma}_o^2$ (1%) indicates that performance was stable across occasions, averaging over persons and items. The nonnegligible $\hat{\sigma}_{po}^2$ (6%) shows that the relative standing of persons differed somewhat across occasions. The zero $\hat{\sigma}_{io}^2$ indicates that the rank ordering of item difficulty was similar across

occasions. Finally, the large $\hat{\sigma}_{pio,e}^2$ (36%) reflects the varying relative standing of persons across occasions and items and/or other sources of error not systematically incorporated into the G study.

Because more of the error variability in science achievement scores came from items than from occasions, changing the number of items will have a larger effect on the estimated variance components and generalizability coefficients than will changing the number of occasions. For example, the estimated G and Phi coefficients for 4 items and 2 occasions are 0.72 and 0.69, respectively; the coefficients for 2 items and 4 occasions are 0.67 and 0.63, respectively. Choosing the number of conditions of each facet in a D study, as well as the design (nested vs. crossed, fixed vs. random facet), involves logistical and cost considerations as well as issues of dependability.

Generalized Additive Model

The **generalized linear model (GLM)** can accommodate nonlinear functions of the explanatory variables, for example, quadratic or cubic terms, if these are considered to be necessary to provide an adequate fit of a model for the observations. An alternative approach is to use a model in which the relationships between the response variable and the explanatory variables are modeled by **scatterplot smoothers**. This leads to generalized additive models described in detail in [1]. Such models are useful where

- the relationship between the variables is expected to be complex, not easily fitted by standard linear or nonlinear models;
- there is no *a priori* reason for using a particular model;
- we would like the data themselves to suggest the appropriate functional form.

Such models should be regarded as being philosophically closer to the concepts of **exploratory data**

analysis in which the form of any functional relationship emerges from the data rather than from a theoretical construct. In psychology, this can be useful because it reflects the uncertainty of the correct model to be applied in many situations.

In generalized additive models, the $\beta_i x_i$ term of **multiple linear regression** and **logistic regression** is replaced by a ‘smooth’ function of the explanatory variable x_i , as suggested by the observed data. Generalized additive models work by replacing the regression coefficients found in other regression models by the fit from one or other of these ‘smoothers’. In this way, the strong assumptions about the relationships of the response to each explanatory variable implicit in standard regression models are avoided. Details of how such models are fitted to data are given in [1].

Generalized additive models provide a useful addition to the tools available for exploring the relationship between a response variable and a set of explanatory variables. Such models allow possible nonlinear terms in the latter to be uncovered and then, perhaps, to be modeled in terms of a suitable, more familiar, low-degree polynomial. Generalized additive models can deal with nonlinearity in covariates that are not of main interest in a study and can ‘adjust’ for such effects appropriately.

Figure 1 Scatterplot matrix of the data on crime in the United States

Figure 2 Form of locally weighted regression fit for crime rate and age [$\text{lo}(\text{age})$ represents the lowess fit—see scatterplot smoothers], and crime rate and unemployment [$\text{lo}(\text{unemployment})$ represents the lowess fit] of locally weighted regression fit for crime rate and age and crime rate and unemployment

As an example of the application of GAMs, we consider some data on crime rates in the United States given in [2]. The question of interest is how crime rate (number of offenses known to the police per one million population) in different states of the United States is related to the age of males in the age group 14 to 24 per 1000 of the total state population and to unemployment in urban males per 1000 population in the age group 14 to 24. A **scatterplot matrix** of the data is shown in Figure 1 and suggests that the relationship between crime rate and each of the other two variables *may* depart from linearity in some subtle fashion that is worth investigating using a GAM. Using a locally weighted regression to model the relationship between crime rate and each of the explanatory variables, the model can be fitted simply using software available in, for example, *SAS* or *S-PLUS* (see **Software for Statistical Analyses**). Rather than giving the results in detail, we simply show the locally weighted fits of crime rate on age and unemployment in Figure 2.

The locally weighted regression fit for age suggests, perhaps, that a linear fit for crime rate on age might be appropriate, with crime declining with an increasingly aged state population. But the relationship between crime rate and unemployment is clearly nonlinear. Use of the GAM suggests, perhaps, that crime rate might be modeled by a multiple regression approach with a linear term for age and a quadratic term for unemployment.

Generalized Estimating Equations (GEE)

Introduction

The usual practice in model construction is the specification of the systematic and random components of variation. Classical **maximum likelihood** models then rely on the validity of the specified components. Model construction proceeds from the (components of variation) specification to a likelihood and, ultimately, an *estimating equation*. The estimating equation for maximum likelihood estimation is obtained by equating zero to the derivative of the log-likelihood with respect to the parameters of interest. Point estimates of unknown parameters are obtained by solving the estimating equation.

Generalized Linear Models

The theory and an algorithm appropriate for obtaining maximum likelihood estimates where the response follows a distribution in the exponential family (see **Generalized Linear Models (GLM)**) was introduced in [16]. This reference introduced the term generalized linear models (GLMs) to refer to a class of models which could be analyzed by a single algorithm. The theoretical and practical application of (GLMs) has since received attention in many articles and books; see especially [14].

GLMs encompass a wide range of commonly used models such as linear regression (see **Multiple Linear Regression**), **logistic regression** for binary outcomes, and Poisson regression (see **Generalized Linear Models (GLM)**) for count data outcomes. The specification of a particular GLM requires a link function that characterizes the relationship of the mean response to a vector of covariates. In addition, a GLM requires specification of a variance function that relates the variance of the outcomes as a function of the mean.

The derivation of the iteratively reweighted least squares (see **Generalized Linear Mixed Models**) (IRLS) algorithm appropriate for fitting GLMs begins with the likelihood specification for the exponential family. Within an iterative algorithm, an updated estimate of the coefficient vector may be obtained via

weighted ordinary least squares where the weights are related to the link and variance specifications. The estimation is then iterated to convergence where convergence may be defined, for example, as the change in the estimated coefficient vector being smaller than some tolerance.

For any response that follows a member of the exponential family of distributions, $f(y) = \exp\{[y\theta - b(\theta)]/\phi + c(y, \phi)\}$, where θ is the canonical parameter and ϕ is a proportionality constant, we can obtain maximum likelihood estimates of the $p \times 1$ regression coefficient vector β by solving the estimating equation given by

$$\Psi_\beta = \sum_{i=1}^n \Psi_i = \sum_{i=1}^n \mathbf{x}_i^T \left\{ \frac{y_i - \mu_i}{\phi V(\mu_i)} \left(\frac{\partial \mu_i}{\partial \eta_i} \right) \right\} = \mathbf{0}_{p \times 1}. \quad (1)$$

In the estimation equation $\mathbf{x}_i$ is the i th row of an $n \times p$ matrix of covariates $\mathbf{X}$, $\mu_i = g^{-1}(\mathbf{x}_i \beta)$ represents the expected outcome $E(y) = b'(\theta)$ in terms of a transformation of the linear predictor $\eta_i = \mathbf{x}_i \beta$ via a monotonic (invertible) link function $g()$, and the variance $V(\mu_i)$ is a function of the expected value proportional to the variance of the outcome $V(y_i) = \phi V(\mu_i)$. The estimating equation is also known as the score equation since it equates the score vector Ψ_β to zero.

Modelers are free to choose a link function (see **Generalized Linear Models (GLM)**) as well as a variance function. If the link-variance pair of functions are chosen from a common member of the exponential family of distributions, the resulting estimates are equivalent to maximum likelihood estimates. However, modelers are not limited to these choices. When one selects variance and link functions that do not coincide to a particular exponential family member distribution, the estimating equation is said to imply a quasilielihood, (see **Generalized Linear Models (GLM)**) and the resulting estimates are referred to as maximum quasilielihood estimates.

The link function that equates the canonical parameter θ with the linear predictor $\eta_i = \mathbf{x}_i \beta$ is called the canonical link. If this link is selected, the estimating equation simplifies to

$$\Psi_\beta = \sum_{i=1}^n \Psi_i = \sum_{i=1}^n \mathbf{x}_i^T \left\{ \frac{y_i - \mu_i}{\phi} \right\} = \mathbf{0}_{p \times 1}. \quad (2)$$

One advantage of the canonical link over other link functions is that the expected Hessian matrix is

equal to the observed Hessian matrix. This means that the model-based variance estimate (inverse of the expected Hessian) usually provided by the IRLS algorithm for GLMs will be the same as the model-based variance estimate (inverse of the observed Hessian) usually provided from a maximum likelihood algorithm. One should note, however, that this property does not automatically mean that the canonical link function is the best choice for a given dataset.

The large sample covariance matrix of the estimated regression coefficients $\hat{\beta}$ may be estimated using the inverse of the expected **information matrix** (the expectation of the matrix outer product of the scores $\sum_{i=1}^n \Psi_i \Psi_i^T$), or the inverse of the observed information matrix (matrix of derivatives of the score vector, $\partial \Psi_{\beta} / \partial \beta$). These two variance estimators, evaluated at $\hat{\beta}$, are the same if the canonical link is used.

The Independence Model

A basic individual-level model is written in terms of the n individual observations y_i for $i = 1, \dots, n$. When observations may be clustered (*see Clustered Data*), owing to repeated observations on the sampling unit or because the observations are related to some cluster identifier variable, the model may be written in terms of the observations y_{it} for the clusters $i = 1, \dots, n$ and the within-cluster repeated, or related, observations $t = 1, \dots, n_i$. The total number of observations is then $N = \sum_i n_i$. The clusters may also be referred to as panels, subjects, or groups. In this presentation, the clusters i are independent, but the within-clusters observations it may be correlated. An independence model, however, assumes that the within-cluster observations are not correlated.

The independence model is a special case of more sophisticated correlated data approaches (such as GEE). This model assumes that there is no correlation within clusters. Therefore, the model specification is in terms of the individual observations y_{it} . While the independence model assumes that the repeated measures are independent, the model still provides consistent estimators in the presence of correlated data. Of course, this approach is paid for through inefficiency, though the efficiency loss is not always large as investigated by Glonek et al. [5]. As such, this model remains an attractive alternative because of its computational simplicity. The independence

model also serves as a reference model in the derivation of diagnostics for more sophisticated models for clustered data (such as GEE models).

Analysts can use the independence model to obtain point estimates $\hat{\beta}$ along with standard errors based on the modified sandwich variance estimator to ensure that inference is robust to any type of within-cluster correlation. While the inference regarding marginal effects is valid (assuming that the model for the mean is correctly specified), the estimator from the independence model is not efficient when the data are correlated.

Modified Sandwich Variance Estimator

The validity of the (naive) model-based variance estimators, using the inverse of either the observed or expected Hessian, depends on the correct specification of the variance; in turn this depends on the correct specification of the working correlation model. A formal justification for an alternative estimator known as the sandwich variance estimator is given in [9].

The sandwich variance estimator is presented in the general form $\mathbf{A}^{-1} \mathbf{B} \mathbf{A}^{-T}$. Here $\mathbf{A}^{-1}$ (the so-called ‘bread’ of the sandwich) is the standard model-based (naive) variance estimator which can be based on the expected Hessian or the observed Hessian (*see Information Matrix*). The $\mathbf{B}$ variance estimator is the sum of the cross-products of the scores.

The $\mathbf{B}$ variance estimator does not depend on the correct specification of the assumed model and is given by $\mathbf{B} = \sum_{i=1}^n \sum_{t=1}^{n_i} \Psi_{it} \Psi_{it}^T$. As the expected value of the estimating equation is zero, this formula is similar to the usual variance estimator. A generalization is obtained by squaring the sums of the terms for each cluster (since we assume that the clusters are independent) instead of summing the squares of the terms for each observation. This summation over clusters $\mathbf{B} = \sum_{i=1}^n [\sum_{t=1}^{n_i} \Psi_{it}] [\sum_{t=1}^{n_i} \Psi_{it}^T]$ is what adds the *modified* adjective to the modified sandwich variance estimator.

The beneficial properties of the sandwich variance estimator, in the usual or the modified form, make it a popular choice for many analysts. However, the acceptance of this estimator is not without some controversy. A discussion of the decreased efficiency and increased variability of the sandwich estimator in common applications is presented in [11], and [3]

argues against blind application of the sandwich estimator by considering an independent samples test of means.

It should be noted that assuming independence is not always conservative; the model-based (naive) variance estimates based on the observed or expected Hessian matrix are not always smaller than those of the modified sandwich variance estimator. Since the sandwich variance estimator is sometimes called the robust variance estimator, this result may seem counterintuitive. However, it is easily seen by assuming negative within-cluster correlation leading to clusters with both positive and negative residuals. The cluster-wise sums of those residuals will be small and the resulting modified sandwich variance estimator will yield smaller standard errors than the model-based Hessian variance estimators.

Subject-specific (SS) versus Population-averaged (PA) Models

There are two main approaches to dealing with correlation in repeated or **longitudinal data**. One approach focuses on the marginal effects averaged across the individuals (*see Marginal Models for Clustered Data*) (population-averaged approach), and the second approach focuses on the effects for given values of the random effects by fitting parameters of the assumed random-effects distribution (subject-specific approach). Formally, we specify a generalized linear mixed model and include a source of the nonindependence. We can then either explicitly model the conditional expectation given the random effects γ_i using $\mu_{it}^{SS} = E(y_{it} | \mathbf{x}_{it}, \gamma_i)$, or we can focus on the marginal expectation (integrated over the distribution of the random effects) as $\mu_{it}^{PA} = E_{\gamma_i}[E(y_{it} | \mathbf{x}_{it}, \gamma_i)]$. The responses in these approaches are characterized by

$$\begin{aligned} g(\mu_{it}^{SS}) &= \mathbf{x}_{it} \boldsymbol{\beta}^{SS} + \mathbf{z}_{it} \gamma_i \\ V(y_{it} | \mathbf{x}_{it}, \gamma_i) &= V(\mu_{it}^{SS}) \\ g(\mu_{it}^{PA}) &= \mathbf{x}_{it} \boldsymbol{\beta}^{PA} \\ V(y_{it} | \mathbf{x}_{it}) &= \phi V(\mu_{it}^{PA}). \end{aligned} \quad (3)$$

The population-averaged approach models the average response for observations sharing the same covariates (across all of the clusters or subjects). The superscripts are used to emphasize that the

fitted coefficients are not the same. The subject-specific approach explicitly models the source of heterogeneity so that the fitted regression coefficients have an interpretation in terms of the individuals.

The most commonly applied GEE is described in [12]. This is a population-averaged approach. It is possible to derive subject-specific GEE models, but such models are not currently part of software packages and so do not appear nearly as often in the literature.

(Population-averaged) Generalized Estimating Equations

The genesis of population-averaged generalized estimating equations is presented in [12]. The basic idea behind this novel approach is illustrated as follows. We consider the estimating equation for a model specifying the exponential family of distributions

$$\begin{aligned} \Psi_{\beta} &= \sum_{i=1}^n \Psi_i = \sum_{i=1}^n \mathbf{X}_i^T \left[\left\{ \mathbf{D} \left(\frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\eta}_i} \right) [\mathbf{V}(\boldsymbol{\mu}_i)]^{-1} \right. \right. \\ &\quad \left. \left. \times \left(\frac{\mathbf{y}_i - \boldsymbol{\mu}_i}{\phi} \right) \right\} \right] = \mathbf{0}_{p \times 1}, \end{aligned} \quad (4)$$

where $\mathbf{D}(\mathbf{d}_i)$ denotes a diagonal matrix with diagonal elements given by the $n_i \times 1$ vector $\mathbf{d}_i$, $\mathbf{X}_i$ is the $n_i \times p$ matrix of covariates for cluster i , and $\mathbf{y}_i = (y_{i1}, \dots, y_{in_i})$ and $\boldsymbol{\mu}_i = (\mu_{i1}, \dots, \mu_{in_i})$ are $n_i \times 1$ vectors for cluster i . Assuming independence, $\mathbf{V}(\boldsymbol{\mu}_i)$ is clearly an $n_i \times n_i$ diagonal matrix which can be factored into

$$\mathbf{V}(\boldsymbol{\mu}_i) = [\mathbf{D}(V(\mu_{it}))^{1/2} \mathbf{I}_{(n_i \times n_i)} \mathbf{D}(V(\mu_{it}))^{1/2}]_{n_i \times n_i}, \quad (5)$$

where $\mathbf{D}(d_{it})$ is a $n_i \times n_i$ diagonal matrix with diagonal elements d_{it} for $t = 1, \dots, n_i$. This presentation makes it clear that the estimating equation treats each observation within a cluster as independent. A (pooled) model associated with this estimating equation is called the *independence model*.

There are two other aspects of the estimating equation to note. The first aspect is that the estimating equation is written in terms of $\boldsymbol{\beta}$ while the scale parameter ϕ is treated as ancillary. For discrete families, this parameter is theoretically equal to one, while for continuous families ϕ is a scalar multiplying the assumed variance (ϕ is estimated in this case).

4 Generalized Estimating Equations (GEE)

The second aspect of the estimating equation to note is that it is written in terms of the clusters i instead of the observations it .

The genesis of the original population-averaged generalized estimating equations is to replace the identity matrix with a parameterized *working correlation matrix* $\mathbf{R}(\alpha)$.

$$\mathbf{V}(\mu_i) = [\mathbf{D}(V(\mu_{it}))^{1/2} \mathbf{R}(\alpha)_{(n_i \times n_i)} \times \mathbf{D}(V(\mu_{it}))^{1/2}]_{n_i \times n_i}. \quad (6)$$

To address correlated data, the working correlation matrix is parameterized via α in order to specify structural constraints section ‘Estimating the Working Correlation Matrix’. In this way, the independence model is a special case of the GEE specifications where $\mathbf{R}(\alpha)$ is an identity matrix.

Formally, [12] introduces a second estimating equation for the parameters of the working correlation matrix. The authors then establish the properties of the estimators resulting from the solution of these estimating equations. The GEE moniker was applied as the model is derived through a generalization of the estimating equation rather than a derivation from some assumed distribution. Example applications of these models in behavioral statistics studies can be found in [4] and [1].

GEE is a generalization of the quasilielihood approach to GLMs which merely uses first and second moments and does not require a likelihood. There are several software packages that support estimation of these models. These packages include R, SAS, S-PLUS, Stata, and SUDAAN. R and S-PLUS users can easily find user-written software tools for fitting GEE models, while such support is included in the other packages (*see Software for Statistical Analyses*).

Estimating the Working Correlation Matrix

One should carefully consider the parameterization of the working correlation matrix since including the correct parameterization leads to more efficient estimates. We want to carefully consider this choice even if we employ the modified sandwich variance estimator in the calculation of standard errors and confidence intervals for the regression parameters. While the use of the modified sandwich variance estimator

assures robustness in the case of misspecification of the working correlation matrix, the advantage of more efficient point estimates is still worth this effort.

There is no controversy as to the fact that the GEE estimates are consistent, but there is some controversy as to how efficient they are. This controversy centers on how well the correlation parameters can be estimated.

The full generalized estimating equation for population-averaged GEEs is given in partitioned form by $\Psi = (\Psi_\beta, \Psi_\alpha) = (\mathbf{0}, \mathbf{0})$, where the regression β and correlation α components are given by

$$\begin{aligned} \Psi_\beta &= \sum_{i=1}^n \mathbf{X}_i^T \left(\frac{\partial \mu_i}{\partial \eta_i} \right) \mathbf{V}^{-1}(\mu_i) \left(\frac{\mathbf{y}_i - \mu_i}{\phi} \right) = \mathbf{0} \\ \Psi_\alpha &= \sum_{i=1}^n \left(\frac{\partial \xi_i}{\partial \alpha} \right) \mathbf{H}_i^{-1} (\mathbf{W}_i - \xi_i) = \mathbf{0}, \end{aligned} \quad (7)$$

where $\mathbf{W}_i = (r_{i1}r_{i2}, r_{i1}r_{i3}, \dots, r_{in_i-1}r_{in_i})^T$, $\mathbf{H}_i = \mathbf{D}(V(\mathbf{W}_i))$, and $\xi_i = E(\mathbf{W}_i)$. From this specification (using r_{it} for the it th Pearson residual), it is clear that the parameterization of the working correlation matrix enters through the specification of ξ . For example, the specification $\xi = (\alpha, \alpha, \dots, \alpha)$ signals a single unknown correlation; we assume that the conditional correlations for all pairs of observations within a given cluster are the sample. For instance, the correlations do not depend on a time lag.

Typically a careful analyst chooses some small number of candidate parameterizations. The quasilielihood information criterion (QIC) measures for choosing between candidate parameterizations is discussed in [17]. This criterion measure is similar to the well known **Akaike information criterion** (AIC).

The most common choices for parameterizing the working correlation $\mathbf{R}$ matrix are then given by parameterizing the elements of the matrix as

$$\begin{aligned} \text{independent} & R_{uv} = 0 \\ \text{exchangeable} & R_{uv} = \alpha \\ \text{autocorrelated} & \\ \quad - \text{AR}(1) & R_{uv} = \alpha^{|u-v|} \\ \text{stationary}(k) & R_{uv} = \begin{cases} \alpha_{|u-v|} & \text{if } |u-v| \leq k \\ 0 & \text{otherwise} \end{cases} \\ \text{nonstationary}(k) & R_{uv} = \begin{cases} \alpha_{uv} & \text{if } |u-v| \leq k \\ 0 & \text{otherwise} \end{cases} \\ \text{unstructured} & R_{uv} = \alpha_{uv} \end{aligned} \quad (8)$$

for $u \neq v$; $R_{uu} = 1$.

The independence model admits no extra parameters and the resulting model is equivalent to a generalized linear model specification. The exchangeable correlation parameterization admits one extra parameter and the unstructured working correlation parameterization admits $\binom{M}{2} - M$ extra parameters where $M = \max\{n_i\}$. The exchangeable correlation specification is also known as *equal correlation*, *common correlation*, and *compound symmetry* (see **Sphericity Test**).

The elements of the working correlation matrix are estimated using the Pearson residuals from the current fit. Estimation alternates between estimating the regression parameters β for the current estimates of α , and then using those β estimates to obtain residuals to update the estimate of α .

In addition to estimating (α, β) , the continuous families also require estimation of the scale parameter ϕ ; this is the same scale parameter as in generalized linear models. Discrete families theoretically define this parameter to be 1, but one can optionally estimate this parameter in the same manner as is required by continuous exponential family members. Software documentation should specify the conditions under which the parameter is either assumed to be known or is estimated.

The usual approach in GLMs for $N = \sum_i n_i$ total observations is to estimate the ϕ scale parameter as $1/N \sum_{i=1}^n \sum_{j=1}^{n_i} r_{ij}^2$, though some software packages will use $(N - p)$, where p is the dimension of β , as the denominator. Software users should understand that this seemingly innocuous difference will lead to slightly different answers in various software packages. The scale parameter is the denominator in the estimation of the correlation parameters and a change in the estimates of the correlation parameters α will lead to slightly different regression coefficient estimates β .

Extensions to the Population-averaged GEE Model

The GEE models described in [12] are so commonly used that analyses simply refer to their application as GEE. However, GEE derivations are not limited to population-averaged models. In fact, generalized estimating equations methods can be applied in the construction of subject-specific

models; see section ‘Subject-specific (SS) versus Population-averaged (PA) Models’ in this entry and [25].

Several areas of research have led to extensions of the original GEE models. The initial extensions were to regression models not usually supported in generalized linear models. In particular, generalized logistic regression models for multinomial logit, cumulative logistic regression models, and ordered outcome models (ordered logistic and ordered probit) have all found support in various statistical software packages.

An extension of the quasiliikelihood such that both partial derivatives have score-like properties is given in [15], and then [7], and later [6], derive an extended generalized estimating equation (EGEE) model from this extended quasiliikelihood. To give some context to this extension, the estimating equation for β does not change, but the estimating equation for α is then

$$\Psi_{\alpha} = \sum_{i=1}^n \left[-(\mathbf{y}_i - \boldsymbol{\mu}_i)^T \frac{\partial \mathbf{V}(\boldsymbol{\mu}_i)^{-1}}{\partial \boldsymbol{\alpha}} (\mathbf{y}_i - \boldsymbol{\mu}_i) + \text{tr} \left(\mathbf{V}(\boldsymbol{\mu}_i) \frac{\partial \mathbf{V}(\boldsymbol{\mu}_i)^{-1}}{\partial \boldsymbol{\alpha}} \right) \right] = \mathbf{0}. \quad (9)$$

The EGEE model is similar to the population-averaged GEE model in that the two estimating equations are assumed to be orthogonal; it is assumed that $\text{Cov}(\beta, \alpha) = \mathbf{0}$ – a property usually referred to in the literature as GEE1.

At the mention of GEE1, it should be obvious that there is another extension to the original GEE model known as GEE2. A model derived from GEE2 does not assume that β and α are uncorrelated. The GEE2, which is not robust against misspecification of the correlation, is a more general approach that has less restrictions and which provides standard errors for the correlation parameters α . Standard errors are not generally available in population-averaged GEE models though one can calculate bootstrap standard errors.

One other extension of note is the introduction of estimating methods that are resistant to **outliers**. One such approach by Preisser and Qaqish [19] generalizes GEE model estimation following the ideas in robust regression. This generalization down-weights outliers to remove exaggerated influence. The estimating equation for the regression coefficients becomes

$$\Psi_{\beta} = \sum_{i=1}^n \mathbf{D} \left(\frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\eta}_i} \right) \mathbf{V}(\boldsymbol{\mu}_i)^{-1} \times \left(\mathbf{w}_i \frac{\mathbf{y}_i - \boldsymbol{\mu}_i}{\phi} - \mathbf{c}_i \right) = \mathbf{0}_{p \times 1}. \quad (10)$$

The usual GEE is a special case where, for all i , the weights $\mathbf{w}_i$ are given by an $n_i \times n_i$ identity matrix and $\mathbf{c}_i$ by a vector of zeros. Typical approaches use Mallows-type weights calculated from influence diagnostics, though other approaches are possible.

Missing Data

Population-averaged GEE models are derived for complete data. If there are missing observations, the models are still applicable if the data are missing completely at random (MCAR).

Techniques for dealing with **missing data** are a source of active research in all areas of statistical modeling, but methods for dealing with missing data are difficult to implement as turnkey solutions. This means that software packages are not likely to support specific solutions to every research problem. An investigation into the missingness of data requires, as a first step, the means for communicating the nature of the missing data.

If data are not missing completely at random, then an application of GEE analysis is performed under a violation of assumptions leading to suspect results and interpretation. Analyses that specifically address data that do not satisfy the MCAR assumption are referred to as *informatively missing* methods; for further discussion see [22] for applications of inverse probability weighting and [10] for additional relevant discussion.

A formal study for modeling missing data due to dropouts is presented in [13], while [22] and [21] each discuss the application of sophisticated semi-parametric methods under non-ignorable missingness mechanisms which extend usual GEE models to provide consistent estimators. One of the assumptions of GEE is that if there is dropout, the dropout mechanism (*see Dropouts in Longitudinal Studies: Methods of Analysis*) does not depend on the values of the outcomes (outcome-dependent dropout), but as [13] points out, such missingness may depend on the values of the fixed covariates (covariate-dependent dropout).

Diagnostics

One of the most prevalent measures for model adequacy is the Akaike information criterion or AIC. An extension of this measure, given in [17], is called the quaslikelihood information criterion (QIC). This measure is useful for comparing models that differ only in the assumed correlation structure. For choosing covariates in the model, [18] introduces the QIC_u measure that plays a similar role for covariate selection in GEE models as the adjusted R^2 plays in regression.

Since the MCAR is an important assumption in GEE models, [2] provides evidence of the utility of the Wald–Wolfowitz nonparametric **run test**. This test provides a formal approach for assessing compliance of a dataset to the MCAR assumption. While this test is useful, one should not forget the basics of exploratory data analysis. The first assessment of the data and the missingness of the data should be subjectively illustrated through standard graphical techniques.

As in GLMs, the careful investigator looks at influence measures of the data. Standard DFBETA and DFFIT residuals introduced in the case of linear regression are generalized for clustered data analysis by considering deletion diagnostics based on deleting a cluster i at a time rather than an observation it at a time. For goodness-of-fit, [26] provides discussion of measures based on entropy (as a proportional reduction in variation), along with discussion in terms of the concordance correlation.

A χ^2 goodness-of-fit test for GEE binomial models is presented in [8]. The basic idea of the test is to group results into deciles and investigate the frequencies as a χ^2 test of the expected and observed counts. As with the original test, analysts should use caution if there are many ties at the deciles since breaking the ties will be a function of the sort order of the data. In other words, the results will be random.

Standard Wald-type hypothesis tests of regression coefficients can be performed using the estimated covariance matrix of the regression parameters. In addition, [23] provides alternative extensions of Wald, Rao (score), and likelihood ratio tests (deviance difference based on the independence model). These tests are available in the SAS commercial packages via specified contrasts.

Example

To highlight the interpretation of GEE analyses and point out the alternate models, we focus on a simple example. The data are given in Table 1.

Table 1 Number of seizures for four consecutive time periods for 59 patients

The data have been analyzed in many forums; data values are also available in [24] (along with other covariates). The data are from a panel study on Progabide treatment of epilepsy. Baseline measures of the number of seizures in an eight-week period were collected and recorded as baseline for 59 patients. Four follow-up two-week periods also counted the number of seizures; these were recorded as s1, s2, s3, and s4. The baseline variable was divided by four in our analyses to put it on the same scale as the follow-up counts. The age variable records the patient's age in years, and the trt variable indicates whether the patient received the Progabide treatment (value recorded as one) or was part of the control group (value recorded as zero).

An obvious approach to analyzing the data is to hypothesize a Poisson model for the number of seizures. Since we have repeated measures (*see Repeated Measures Analysis of Variance*), we can choose a number of alternative approaches. In our illustrations of these alternative models, we utilize the baseline measure as a covariate along with the time and age variables.

Table 2 contains the results of several analyses. For each covariate, we list the estimated incidence rate ratio (exponentiated coefficient). Following the incidence rate ratio estimates, we list the classical and sandwich-based estimated standard errors. We did not calculate sandwich-based standard errors for the gamma-distributed random-effects model.

We emphasize again that the independence model coupled with standard errors based on the modified sandwich variance estimator is a valid approach

8 Generalized Estimating Equations (GEE)

Table 2 Estimated incidence rate ratios and standard errors for various Poisson models

Model	time	trt	age	baseline
Independence	0.944 (0.019,0.033)	0.832 (0.039,0.143)	1.019 (0.003,0.010)	1.095 (0.002,0.006)
Gamma RE	0.944 (0.019)	0.810 (0.124)	1.013 (0.011)	1.116 (0.015)
Normal RE	0.944 (0.019,0.033)	0.760 (0.117,0.117)	1.011 (0.011,0.009)	1.115 (0.012,0.011)
GEE(exch)	0.944 (0.015,0.033)	0.834 (0.058,0.141)	1.019 (0.005,0.010)	1.095 (0.003,0.006)
GEE(ar1)	0.939 (0.019,0.019)	0.818 (0.054,0.054)	1.021 (0.005,0.003)	1.097 (0.003,0.003)
GEE(unst)	0.951 (0.017,0.041)	0.832 (0.055,0.108)	1.019 (0.005,0.009)	1.095 (0.003,0.005)

to modeling data of this type. The weakness of the approach is that the estimators will not be as efficient as a model including the true underlying within-cluster correlation structure. Another standard approach to modeling this type of repeated measures is to hypothesize that the correlations are due to individual-specific random intercepts (*see Generalized Linear Mixed Models*). These random effects (one could also hypothesize fixed effects) will lead to alternate models for the data.

Results from two different random-effects models are included in the table. The gamma-distributed random-effects model is rather easy to program and fit to data as the log-likelihood of the model is in analytic form. The normally distributed random-effects model on the other hand has a log-likelihood specification that includes an integral. Sophisticated numeric techniques are required for the calculation of this model; see [20].

We could hypothesize that the correlation follows an autoregressive process since the data are collected over time. However, this is not always the best choice in an experiment since we must believe that the hypothesized correlation structure applies to both the treated and untreated groups.

The QIC values for the independence, exchangeable, ar1, and unstructured correlation structures are respectively given by -5826.23 , -5826.25 , -5832.20 , and -5847.91 . This criterion measure indicates a preference for the unstructured model over the autoregressive model. The fitted correlation matrices for these models (printing only the bottom half of the symmetric matrices) are given by

$$R_{AR(1)} = \begin{bmatrix} 1.00 & & & \\ 0.51 & 1.00 & & \\ 0.26 & 0.51 & 1.00 & \\ 0.13 & 0.26 & 0.51 & 1.00 \end{bmatrix}$$

$$R_{unst} = \begin{bmatrix} 1.00 & & & \\ 0.25 & 1.00 & & \\ 0.42 & 0.68 & 1.00 & \\ 0.22 & 0.28 & 0.58 & 1.00 \end{bmatrix}. \quad (11)$$

Generalized Linear Mixed Models

Introduction

Generalized linear models (GLMs) represent a class of fixed effects regression models for several types of dependent variables (i.e., continuous, dichotomous, counts). McCullagh and Nelder [32] describe these in great detail and indicate that the term ‘generalized linear model’ is due to Nelder and Wedderburn [35] who described how a collection of seemingly disparate statistical techniques could be unified. Common Generalized linear models (GLMs) include linear regression, **logistic regression**, and Poisson regression.

There are three specifications in a GLM. First, the linear predictor, denoted as η_i , of a GLM is of the form

$$\eta_i = \mathbf{x}_i' \boldsymbol{\beta}, \quad (1)$$

where $\mathbf{x}_i$ is the vector of regressors for unit i with fixed effects $\boldsymbol{\beta}$. Then, a link function $g(\cdot)$ is specified which converts the expected value μ_i of the outcome variable Y_i (i.e., $\mu_i = E[Y_i]$) to the linear predictor η_i

$$g(\mu_i) = \eta_i. \quad (2)$$

Finally, a specification for the form of the variance in terms of the mean μ_i is made. The latter two specifications usually depend on the distribution of the outcome Y_i , which is assumed to fall within the exponential family of distributions.

Fixed effects models, which assume that all observations are independent of each other, are not appropriate for analysis of several types of correlated data structures, in particular, for clustered and/or longitudinal data (see **Clustered Data**). In clustered designs, subjects are observed nested within larger units, for example, schools, hospitals, neighborhoods, workplaces, and so on. In longitudinal designs, repeated observations are nested within subjects (see **Longitudinal Data Analysis; Repeated Measures Analysis of Variance**). These are often referred to as multi-level [16] or hierarchical [41] data (see **Linear Multilevel Models**), in which the level-1 observations (subjects or repeated observations) are nested within the higher level-2 observations (clusters or subjects).

Higher levels are also possible, for example, a three-level design could have repeated observations (level-1) nested within subjects (level-2) who are nested within clusters (level-3).

For analysis of such multilevel data, random cluster and/or subject effects can be added into the regression model to account for the correlation of the data. The resulting model is a mixed model including the usual fixed effects for the regressors plus the random effects. Mixed models for continuous normal outcomes have been extensively developed since the seminal paper by Laird and Ware [28]. For nonnormal data, there have also been many developments, some of which are described below. Many of these developments fall under the rubric of generalized linear mixed models (GLMMs), which extend GLMs by the inclusion of random effects in the predictor. Agresti et al. [1] describe a variety of social science applications of GLMMs; [12], [33], and [11] are recent texts with a wealth of statistical material on GLMMs.

Let i denote the level-2 units (e.g., subjects) and let j denote the level-1 units (e.g., nested observations). The focus will be on longitudinal designs here, but the methods apply to clustered designs as well. Assume there are $i = 1, \dots, N$ subjects (level-2 units) and $j = 1, \dots, n_i$ repeated observations (level-1 units) nested within each subject. A random-intercept model, which is the simplest mixed model, augments the linear predictor with a single random effect for subject i ,

$$\eta_{ij} = \mathbf{x}_{ij}' \boldsymbol{\beta} + v_i, \quad (3)$$

where v_i is the random effect (one for each subject). These random effects represent the influence of subject i on his/her repeated observations that is not captured by the observed covariates. These are treated as random effects because the sampled subjects are thought to represent a population of subjects, and they are usually assumed to be distributed as $\mathcal{N}(0, \sigma_v^2)$. The parameter σ_v^2 indicates the variance in the population distribution, and therefore the degree of heterogeneity of subjects.

Including the random effects, the expected value of the outcome variable, which is related to the linear predictor via the link function, is given as

$$\mu_{ij} = E[Y_{ij} | v_i, \mathbf{x}_{ij}]. \quad (4)$$

This is the expectation of the conditional distribution of the outcome given the random effects. As a

2 Generalized Linear Mixed Models

result, GLMMs are often referred to as conditional models in contrast to the marginal generalized estimating equations (GEE) models (*see Generalized Estimating Equations (GEE)*) [29], which represent an alternative generalization of GLMs for correlated data (*see Marginal Models for Clustered Data*).

The model can be easily extended to include multiple random effects. For example, in longitudinal problems, it is common to have a random subject intercept and a random linear time-trend. For this, denote $\mathbf{z}_{ij}$ as the $r \times 1$ vector of variables having random effects (a column of ones is usually included for the random intercept). The vector of random effects $\mathbf{v}_i$ is assumed to follow a multivariate normal distribution with mean vector $\mathbf{0}$ and variance–covariance matrix Σ_v (*see Catalogue of Probability Density Functions*). The model is now written as

$$\eta_{ij} = \mathbf{x}_{ij}'\boldsymbol{\beta} + \mathbf{z}_{ij}'\mathbf{v}_i. \quad (5)$$

Note that the conditional mean μ_{ij} is now specified as $E[Y_{ij}|\mathbf{v}_i, \mathbf{x}_{ij}]$, namely, in terms of the vector of random effects.

Dichotomous Outcomes

Development of GLMMs for dichotomous data has been an active area of statistical research. Several approaches, usually adopting a logistic or probit regression model (*see Probits*) and various methods for incorporating and estimating the influence of the random effects, have been developed. A review article by Pendergast et al. [37] discusses and compares many of these developments.

The mixed-effects logistic regression model is a common choice for analysis of multilevel dichotomous data and is arguably the most popular GLMM. In the GLMM context, this model utilizes the logit link, namely

$$g(\mu_{ij}) = \text{logit}(\mu_{ij}) = \log \left[\frac{\mu_{ij}}{1 - \mu_{ij}} \right] = \eta_{ij}. \quad (6)$$

Here, the conditional expectation $\mu_{ij} = E(Y_{ij}|\mathbf{v}_i, \mathbf{x}_{ij})$ equals $P(Y_{ij} = 1|\mathbf{v}_i, \mathbf{x}_{ij})$, namely, the conditional probability of a response given the random effects (and covariate values).

This model can also be written as

$$P(Y_{ij} = 1|\mathbf{v}_i, \mathbf{x}_{ij}, \mathbf{z}_{ij}) = g^{-1}(\eta_{ij}) = \Psi(\eta_{ij}), \quad (7)$$

where the inverse link function $\Psi(\eta_{ij})$ is the logistic cumulative distribution function (cdf), namely $\Psi(\eta_{ij}) = [1 + \exp(-\eta_{ij})]^{-1}$. A nicety of the logistic distribution, that simplifies parameter estimation, is that the probability density function (pdf) is related to the cdf in a simple way, as $\psi(\eta_{ij}) = \Psi(\eta_{ij})[1 - \Psi(\eta_{ij})]$.

The probit model, which is based on the standard normal distribution, is often proposed as an alternative to the logistic model [13]. For the probit model, the normal cdf and pdf replace their logistic counterparts. A useful feature of the probit model is that it can be used to yield **tetrachoric correlations** for the clustered binary responses, and **polychoric correlations** for ordinal outcomes (discussed below). For this reason, in some areas, for example familial studies, the probit formulation is often preferred to its logistic counterpart.

Example

Gruder et al. [20] describe a smoking-cessation study in which 489 subjects were randomized to either a control, discussion, or social support conditions. Control subjects received a self-help manual and were encouraged to watch twenty segments of a daily TV program on smoking cessation, while subjects in the two experimental conditions additionally participated in group meetings and received training in support and relapse prevention. Here, for simplicity, these two experimental conditions will be combined. Data were collected at four telephone interviews: postintervention, and 6, 12, and 24 months later. Smoking abstinence rates (and sample sizes) at these four timepoints were 17.4% (109), 7.2% (97), 18.5% (92), and 18.2% (77) for the placebo condition. Similarly, for the combined experimental condition it was 34.5% (380), 18.2% (357), 19.6% (337), and 21.7% (295) for these timepoints.

Two logistic GLMM were fit to these data: a random intercept and a random intercept and linear trend of time model (*see Growth Curve Modeling*). These models were estimated using SAS PROC NLMIXED with adaptive quadrature. For these, it is the probability of smoking abstinence, rather than smoking, that is being modeled. Fixed effects included a condition term (0 = control, 1 = experimental), time (coded 0, 1, 2, and 4 for the four timepoints), and the condition by time interaction. Results for both models are presented in Table 1. Based on a likelihood-ratio

Table 1 Smoking cessation study: smoking status (0 = smoking, 1 = not smoking) across time (N = 489), GLMM logistic parameter estimates (Est.), standard errors (SE), and *P* values

Parameter	Random intercept model			Random int and trend model		
	Est.	SE	<i>P</i> value	Est.	SE	<i>P</i> value
Intercept	−2.867	.362	.001	−2.807	.432	.001
Time	.113	.122	.36	−.502	.274	.07
Condition (0 = control; 1 = experimental)	1.399	.379	.001	1.495	.415	.001
Condition by Time	−.322	.136	.02	−.331	.249	.184
Intercept variance	3.587	.600		3.979	1.233	
Intercept Time covariance				.048	.371	
Time variance				1.428	.468	
−2 log likelihood		1631.0			1594.7	

Note: *P* values not given for variance and covariance parameters (see [41]).

test, the model with random intercept and linear time trend is preferred over the simpler random intercept model ($\chi^2_2 = 36.3$). Thus, there is considerable evidence for subjects varying in both their intercepts and time trends. It should be noted that the test statistic does not have a chi-square distribution when testing variance parameters because the null hypothesis is on the border of the parameter space, making the *P* value conservative. Snijders and Bosker [46] elaborate on this issue and point out that a simple remedy, that has been shown to be reasonable in simulation studies, is to divide the *P* value based on the likelihood-ratio chi-square test statistic by two. In the present case, it doesn't matter because the *P* value is $<.001$ for $\chi^2_2 = 36.3$ even without dividing by two.

In terms of the fixed effects, both models indicate a nonsignificant time effect for the control condition, and a highly significant condition effect at time 0 (e.g., $z = 1.495/.415 = 3.6$ in the second model). This indicates a positive effect of the experimental conditions on smoking abstinence relative to control at postintervention. There is also some evidence of a negative condition by time interaction, suggesting that the beneficial condition effect diminishes across time. Note that this interaction is not significant ($P < .18$) in the random intercept and trend model, but it is significant in the random intercept model ($P < .02$). Since the former is preferred by the likelihood-ratio test, we would conclude that the interaction is not significant.

This example shows that the significance of model terms can depend on the structure of the random effects. Thus, one must decide upon a reasonable model for the random effects as well as for the fixed effects. A commonly recommended approach

for this is to perform a sequential procedure for model selection. First, one includes all possible covariates of interest into the model and selects between the possible models of random effects using likelihood-ratio tests and model fit criteria. Then, once a reasonable random effects structure is selected, one trims model covariates in the usual way.

IRT Models

Because the logistic model is based on the logistic response function, and the random effects are assumed normally distributed, this model and models closely related to it are often referred to as logistic/normal models, especially in the latent trait model literature [4]. Similarly, the probit model is sometimes referred to as a normal/normal model. In many respects, latent trait or **item response theory** (IRT) models, developed in the educational testing and psychometric literatures, represent some of the earliest GLMMs. Here, item responses ($j = 1, 2, \dots, n$) are nested within subjects ($i = 1, 2, \dots, N$). The simplest IRT model is the **Rasch model** [40] which posits the probability of a correct response to the dichotomous item j ($Y_{ij} = 1$) conditional on the random effect or 'ability' of subject i (θ_i) in terms of the logistic cdf as

$$P(Y_{ij} = 1|\theta_i) = \Psi(\theta_i - b_j), \quad (8)$$

where b_j is the threshold or difficulty parameter for item j (i.e., item difficulty). Subject's ability is commonly denoted as θ in the IRT literature (i.e., instead of ν). Note that the Rasch model is simply a random-intercepts model that includes

4 Generalized Linear Mixed Models

item dummies as fixed regressors. Because there is only one parameter per item, the Rasch model is also called the *one-parameter IRT model*. A more general IRT model, the two-parameter model [5], also includes a parameter for the discrimination of the item in terms of ability.

Though IRT models were not originally cast as GLMMs, formulating them in this way easily allows covariates to enter the model at either level (i.e., items or subjects). This and other advantages of casting IRT models as mixed models are described by Rijmen et al. [43], who provide a comprehensive overview and bridge between IRT models, mixed models, and GLMMs. As they point out, the Rasch model, and variants of it, belong to the class of GLMMs. However, the more extended two-parameter model is not within the class of GLMMs because the predictor is no longer linear, but includes a product of parameters.

Ordinal Outcomes

Extending the methods for dichotomous responses to ordinal response data has also been actively pursued; Agresti and Natarajan [2] review many of these developments. Because the proportional odds model described by McCullagh [31], which is based on the logistic regression formulation, is a common choice for analysis of ordinal data, many of the GLMMs for ordinal data are generalizations of this model, though models relaxing this assumption have also been described [27]. The proportional odds model expresses the ordinal responses in C categories ($c = 1, 2, \dots, C$) in terms of $C - 1$ cumulative category comparisons, specifically, $C - 1$ cumulative logits (i.e., log odds). Here, denote the conditional cumulative probabilities for the C categories of the outcome Y_{ij} as $P_{ijc} = P(Y_{ij} \leq c | \mathbf{v}_i, \mathbf{x}_{ij}) = \sum_{c=1}^C p_{ijc}$, where p_{ijc} represents the conditional probability of response in category c . The logistic GLMM for the conditional cumulative probabilities $\mu_{ijc} = P_{ijc}$ is given in terms of the cumulative logits as

$$\log \left[\frac{\mu_{ijc}}{1 - \mu_{ijc}} \right] = \eta_{ijc} \quad (c = 1, \dots, C - 1), \quad (9)$$

where the linear predictor is now

$$\eta_{ijc} = \gamma_c - [\mathbf{x}'_{ij}\boldsymbol{\beta} + \mathbf{z}'_{ij}\mathbf{v}_i], \quad (10)$$

with $C - 1$ strictly increasing model thresholds γ_c (i.e., $\gamma_1 < \gamma_2 < \dots < \gamma_{C-1}$). The thresholds allow the cumulative response probabilities to differ. For identification, either the first threshold γ_1 or the model intercept β_0 is typically set to zero. As the regression coefficients $\boldsymbol{\beta}$ do not carry the c subscript, the effects of the regressors do not vary across categories. McCullagh [31] calls this assumption of identical odds ratios across the $C - 1$ cutoffs the proportional odds assumption.

Because the ordinal model is defined in terms of the cumulative probabilities, the conditional probability of a response in category c is obtained as the difference of two conditional cumulative probabilities:

$$P(Y_{ij} = c | \mathbf{v}_i, \mathbf{x}_{ij}, \mathbf{z}_{ij}) = \Psi(\eta_{ijc}) - \Psi(\eta_{ij,c-1}). \quad (11)$$

Here, $\gamma_0 = -\infty$ and $\gamma_C = \infty$, and so $\Psi(\eta_{ij0}) = 0$ and $\Psi(\eta_{ijC}) = 1$ (see **Ordinal Regression Models**).

Example

Hedeker and Gibbons [25] described a random-effects ordinal probit regression model, examining longitudinal data collected in the NIMH Schizophrenia Collaborative Study on treatment related changes in overall severity. The dependent variable was item 79 of the Inpatient Multidimensional Psychiatric Scale (IMPS; [30]), scored as: (a) normal or borderline mentally ill, (b) mildly or moderately ill, (c) markedly ill, and (d) severely or among the most extremely ill. In this study, patients were randomly assigned to receive one of four medications: placebo, chlorpromazine, fluphenazine, or thioridazine. Since previous analyses revealed similar effects for the three antipsychotic drug groups, they were combined in the analysis. The experimental design and corresponding sample sizes are listed in Table 2.

As can be seen from Table 2, most of the measurement occurred at weeks 0, 1, 3, and 6, with some scattered measurements at the remaining timepoints.

Table 2 Experimental design and weekly sample sizes

Group	Sample size at week						
	0	1	2	3	4	5	6
Placebo (n = 108)	107	105	5	87	2	2	70
Drug (n = 329)	327	321	9	287	9	7	265

Note: Drug = Chlorpromazine, Fluphenazine, or Thioridazine.

Table 3 NIMH Schizophrenia Collaborative Study: severity of illness (IMPS79) across time ($N = 437$), GLMM logistic parameter estimates (Est.), standard errors (SE), and P values

Parameter	Est.	SE	P value
Intercept	7.283	.467	.001
Time (sqrt week)	-.879	.216	.001
Drug (0 = placebo; 1 = drug)	.056	.388	.88
Drug by Time	-1.684	.250	.001
Threshold 2	3.884	.209	.001
Threshold 3	6.478	.290	.001
Intercept variance	6.847	1.282	
Intercept-time covariance	-1.447	.515	
Time variance	1.949	.404	
-2 log likelihood		3326.5	

Note: Threshold 1 set to zero for identification. P values not given for variance and covariance parameters (see [41]). NIMH = National Institute of Mental Health; IMPS79 = Inpatient Multidimensional Psychiatric Scale, Item 79.

Here, a logistic GLMM with random intercept and trend was fit to these data using SAS PROC NLMIXED with adaptive quadrature. Fixed effects included a dummy-coded drug effect (placebo = 0 and drug = 1), a time effect (square root of week; this was used to linearize the relationship between the cumulative logits and week) and a drug by time interaction. Results from this analyses are given in Table 3.

The results indicate that the treatment groups do not significantly differ at baseline (drug effect), the placebo group does improve over time (significant negative time effect), and the drug group has greater improvement over time relative to the placebo group (significant negative drug by time interaction). Thus, the analysis supports use of the drug, relative to placebo, in the treatment of schizophrenia.

Comparing this model to a simpler random-intercepts model (not shown) yields clear evidence of significant variation in both the individual intercept and time-trends (likelihood-ratio $\chi^2_2 = 77.7$). Also, a moderate negative association between the intercept and linear time terms is indicated, expressed as a correlation it equals $-.40$, suggesting that those patients with the highest initial severity show the greatest improvement across time (e.g., largest negative time-trends). This latter finding could be a result of a ‘floor effect’, in that patients with low initial severity scores cannot exhibit large negative time-trends due to the limited range in the ordinal outcome variable. Finally, comparing this model to one that allows

nonproportional odds for all model covariates (not shown) supports the proportional odds assumption ($\chi^2_6 = 3.63$). Thus, the three covariates (drug, time, and drug by time) have similar effects on the three cumulative logits.

Survival Analysis Models

Connections between ordinal regression and survival analysis models (see **Survival Analysis**) have led to developments of discrete and grouped-time survival analysis GLMMs [49]. The basic notion is that the time to the event can be considered as an ordinal variable with C possible event times, albeit with right-censoring accommodated. Vermunt [50] also describes related log-linear mixed models for survival analysis or **event history analysis**.

Nominal Outcomes

Nominal responses occur when the categories of the response variable are not ordered. General regression models for multilevel nominal data have been considered, and Hartzel et al. [22] synthesizes much of the work in this area, describing a general mixed-effects model for both clustered ordinal and nominal responses.

In the nominal GLMM, the probability that $Y_{ij} = c$ (a response occurs in category c) for a given individual i , conditional on the random effects $\mathbf{v}$, is given by:

$$p_{ijc} = P(Y_{ij} = c | \mathbf{v}_i, \mathbf{x}_{ij}, \mathbf{z}_{ij}) = \frac{\exp(\eta_{ijc})}{1 + \sum_{h=1}^C \exp(\eta_{ijh})} \text{ for } c = 2, 3, \dots, C, \quad (12)$$

$$p_{ij1} = P(Y_{ij} = 1 | \mathbf{v}_i, \mathbf{x}_{ij}, \mathbf{z}_{ij}) = \frac{1}{1 + \sum_{h=1}^C \exp(\eta_{ijh})}, \quad (13)$$

with the linear predictor $\eta_{ijc} = \mathbf{x}_{ij}'\boldsymbol{\beta}_c + \mathbf{z}_{ij}'\mathbf{v}_{ic}$. Both the regression coefficients $\boldsymbol{\beta}_c$ and the random-effects carry the c subscript; the latter allows the variance-covariance matrix $\boldsymbol{\Sigma}_{v_c}$ to vary across categories. In the model above, these parameters represent differences relative to the first category. The nominal model can also be written to allow for any possible set of $C - 1$ contrasts, see [24] for an example of this.

Ranks

In ranking data, individuals are asked to rank C distinct options with respect to some criterion. If the individuals are only asked to provide the option with the highest (or lowest) rank of the C categories, then the resulting data consist of either an ordinal outcome (if the C options are ordered) or a nominal outcome (if the C options are not ordered), and analysis can proceed using the models described above. In the more general case, individuals are asked for, say, the top three options, or to fully rank the C options from the ‘best’ to the ‘worst’ (i.e., all options receive a rank from 1 to C). The former case consists of partial ranking data, while the latter case represents full ranking data. As these data types are generalizations of nominal and ordinal data types, it is not surprising that statistical models for ranking data are generalizations of the models for ordinal and nominal models described above. In particular, since the C options are usually not ordered options, models for ranking data have close connections with models for nominal outcomes. GLMMs for ranking data are described in [6] and [45]. These articles show the connections between models for multilevel nominal and ranking data, as well as develop several extensions for the latter.

Counts

For count data, various types of Poisson mixed models have been proposed. A review of some of these methods applied to longitudinal Poisson data is given in [47]. For computational purposes, it is convenient for the univariate random effects to have a gamma distribution in the population of subjects [3]. However, as described in [11], adding multiple normally distributed random effects on the same scale as the fixed effects of the Poisson regression model provides a more general and flexible model.

Let Y_{ij} be the value of the count variable (where Y_{ij} can equal $0, 1, \dots$) associated with individual i and timepoint j . If this count is assumed to be drawn from a Poisson distribution, then the mixed Poisson regression model indicates the expected number of counts as

$$\log \mu_{ij} = \eta_{ij}, \quad (14)$$

with the linear predictor $\eta_{ij} = \mathbf{x}_{ij}'\boldsymbol{\beta} + \mathbf{z}_{ij}'\mathbf{v}_i$. In some cases the size of the time interval over which the events are counted varies. For example, McKnight and Van Den Eeden [34] describe a study in which the number of headaches in a week is recorded, however, not all individuals are measured for all seven days. For this, let t_{ij} represent the follow-up time associated with units i and j . The linear predictor is now augmented as

$$\eta_{ij} = \log t_{ij} + \mathbf{x}_{ij}'\boldsymbol{\beta} + \mathbf{z}_{ij}'\mathbf{v}_i, \quad (15)$$

which can also be expressed as

$$\mu_{ij} = t_{ij} \exp(\mathbf{x}_{ij}'\boldsymbol{\beta} + \mathbf{z}_{ij}'\mathbf{v}_i) \quad (16)$$

or $\mu_{ij}/t_{ij} = \exp(\mathbf{x}_{ij}'\boldsymbol{\beta} + \mathbf{z}_{ij}'\mathbf{v}_i)$ to reflect that it is the number of counts per follow-up period that is being modeled. The term $\log t_{ij}$ is often called an *offset*.

Assuming the Poisson process for the count Y_{ij} , the probability that $Y_{ij} = y$, conditional on the random effects $\mathbf{v}$, is given as

$$P(Y_{ij} = y | \mathbf{v}_i, \mathbf{x}_{ij}, \mathbf{z}_{ij}) = \exp(-\mu_{ij}) \frac{(\mu_{ij})^y}{y!}. \quad (17)$$

It is often the case that count data exhibit more zero counts than what is consistent with the Poisson distribution. For such situations, zero-inflated Poisson (ZIP) mixed models, which contain a logistic (or probit) regression for the probability of a nonzero response and a Poisson regression for the zero

and nonzero counts, have been developed [21]. A somewhat related model is described by Olsen and Schafer [36] who propose a two-part model that includes a logistic model for the probability of a nonzero response and a conditional linear model for the mean response given that it is nonzero.

Estimation

Parameter estimation in GLMMs typically involves **maximum likelihood** (ML) or variants of ML. Additionally, the solutions are usually iterative ones that can be numerically quite intensive. Here, the solution is merely sketched; further details can be found in [33] and [12].

For the models presented, (7), (11), (12)–(13), and (17), indicate the probability of a level-1 response Y_{ij} for a given subject i at timepoint j , conditional on the random effects $\mathbf{v}_i$. While the form of this probability depends on the form of the response variable, let $P(Y_{ij}|\mathbf{v}_i)$ represent the conditional probability for any of these forms. Here, for simplicity, we omit conditioning on the covariates $\mathbf{x}_{ij}$. Let $\mathbf{Y}_i$ denote the vector of responses from subject i . The probability of any response pattern $\mathbf{Y}_i$ (of size n_i), conditional on $\mathbf{v}_i$, is equal to the product of the probabilities of the level-1 responses:

$$\ell(\mathbf{Y}_i|\mathbf{v}_i) = \prod_{i=1}^{n_i} P(Y_{ij}|\mathbf{v}_i). \quad (18)$$

The assumption that a subject's responses are independent given the random effects (and therefore can be multiplied to yield the conditional probability of the response vector) is known as the **conditional independence** assumption. The marginal density of $\mathbf{Y}_i$ in the population is expressed as the following integral of the conditional likelihood $\ell(\cdot)$

$$h(\mathbf{Y}_i) = \int_{\mathbf{v}_i} \ell(\mathbf{Y}_i|\mathbf{v}_i) f(\mathbf{v}_i) d\mathbf{v}_i, \quad (19)$$

where $f(\mathbf{v}_i)$ represents the distribution of the random effects, often assumed to be a multivariate normal density. Whereas (18) represents the conditional probability, (19) indicates the unconditional probability for the response vector of subject i . The marginal log-likelihood from the sample of N subjects is then obtained as $\log L = \sum_i^N \log h(\mathbf{Y}_i)$. Maximizing this

log-likelihood yields ML estimates (which are sometimes referred to as maximum marginal likelihood estimates) of the regression coefficients $\boldsymbol{\beta}$ and the variance-covariance matrix of the random effects $\boldsymbol{\Sigma}_{\mathbf{v}_i}$.

Integration over the random-effects distribution

In order to solve the likelihood solution, integration over the random-effects distribution must be performed. As a result, estimation is much more complicated than in models for continuous normally distributed outcomes where the solution can be expressed in closed form. Various approximations for evaluating the integral over the random-effects distribution have been proposed in the literature; many of these are reviewed in [44]. Perhaps the most frequently used methods are based on first- or second-order Taylor expansions. Marginal quasi-likelihood (MQL) involves expansion around the fixed part of the model, whereas penalized or predictive quasi-likelihood (PQL) additionally includes the random part in its expansion [17]. Unfortunately, these procedures yield estimates of the regression coefficients and random effects variances that are biased towards zero in certain situations, especially for the first-order expansions [7].

More recently, Raudenbush et al. [42] proposed an approach that uses a combination of a fully multivariate Taylor expansion and a Laplace approximation. This method yields accurate results and is computationally fast. Also, as opposed to the MQL and PQL approximations, the deviance obtained from this approximation can be used for likelihood-ratio tests.

Numerical integration can also be used to perform the integration over the random-effects distribution. Specifically, if the assumed distribution is normal, Gauss–Hermite quadrature can approximate the above integral to any practical degree of accuracy. Additionally, like the Laplace approximation, the numerical quadrature approach yields a deviance that can be readily used for likelihood-ratio tests. The integration is approximated by a summation on a specified number of quadrature points for each dimension of the integration. An issue with the quadrature approach is that it can involve summation over a large number of points, especially as the number of random-effects is increased. To address this, methods of adaptive quadrature have been developed which use a few points per dimension that are adapted

to the location and dispersion of the distribution to be integrated [39].

More computer-intensive methods, involving iterative simulations, can also be used to approximate the integration over the random effects distribution. Such methods fall under the rubric of **Markov chain Monte Carlo** (MCMC; [15]) algorithms. Use of MCMC for estimation of a wide variety of models has exploded in the last 10 years or so; MCMC solutions for GLMMs are described in [9].

Estimation of random effects

In many cases, it is useful to obtain estimates of the random effects. The random effects v_i can be estimated using empirical Bayes methods (*see Random Effects in Multivariate Linear Models: Prediction*). For the univariate case, this estimator $\hat{v}_i$ is given by:

$$\hat{v}_i = E(v_i | Y_i) = h_i^{-1} \int_{v_i} v_i \ell_i f(v_i) dv_i \quad (20)$$

where ℓ_i is the conditional probability for subject i under the particular model and h_i is the analogous marginal probability. This is simply the mean of the posterior distribution. Similarly, the variance of the posterior distribution is obtained as

$$V(\hat{v}_i | Y_i) = h_i^{-1} \int_{v_i} (v_i - \hat{v}_i)^2 \ell_i f(v_i) dv_i. \quad (21)$$

These quantities may then be used, for example, to evaluate the response probabilities for particular subjects (e.g., person-specific trend estimates). Also, Ten Have [48] suggests how these empirical Bayes estimates can be used in performing residual diagnostics.

Discussion

Though the focus here has been on two-level GLMMs for nonnormal data, three-level (and higher) generalizations have also been considered in the literature [14]. Also, software for fitting GLMMs is readily available in the major statistical packages (i.e., SAS PROC NL MIXED, STATA) and in several independent programs (HLM, [8]; EGRET, [10]; MLwiN, [18]; LIMDEP, [19]; MIXOR, [26]; MIXNO, [23]; GLLAMM, [38]). Not all of these programs fit all of the GLMMs described here; some only allow

random-intercepts models or two-level models, for example, and several vary in terms of how the integration over the random effects is performed. However, though the availability of these software programs is relatively recent, they have definitely facilitated application of GLMMs in psychology and elsewhere. The continued development of these models and their software implementations should only lead to greater use and understanding of GLMMs for analysis of correlated nonnormal data.

Acknowledgments

Thanks are due to Dr. Robin Mermelstein for use of the smoking-cessation study data, and to Drs. Nina Schooler and John Davis for use of the schizophrenia study data. This work was supported by National Institutes of Mental Health Grant MH56146.

Generalized Linear Models (GLM)

The generalized linear model (GLM) is essentially a unified framework for regression models introduced in a landmark paper by Nelder and Wedderburn [7] over 30 years ago. A wide range of statistical models including **analysis of variance**, **analysis of covariance**, **multiple linear regression**, and **logistic regression** are included in the GLM framework. A comprehensive technical account of the model is given in [6], with a more concise description appearing in [2] and [1].

Regression

The term ‘regression’ was first introduced by **Francis Galton** in the nineteenth century to characterize a tendency to mediocrity, that is, towards the average, observed in the offspring of parent seeds, and used by **Karl Pearson** in a study of the heights of fathers and sons. The sons’ heights tended, on average, to be less extreme than the fathers (*see Regression to the Mean*). In essence, all forms of regression have as their aim the development and assessment of a mathematical model for the relationship between a response variable, y , and a set of q explanatory variables (sometimes confusingly referred to as independent variables), $x_1, x_2, \dots, x_q$. Multiple linear regression, for example, involves the following model for y :

$$y = \beta_0 + \beta_1 x_1 + \dots + \beta_q x_q + \varepsilon, \quad (1)$$

where $\beta_0, \beta_1, \dots, \beta_q$ are regression coefficients that have to be estimated from sample data and ε is an error term assumed normally distributed with zero mean and variance σ^2 .

An equivalent way of writing the multiple regression model is:

$$y \sim N(\mu, \sigma^2),$$

where $\mu = \beta_0 + \beta_1 x_1 + \dots + \beta_q x_q$. This makes it clear that this model is only suitable for continuous response variables with, conditional on the values of the explanatory variables, a normal distribution with constant variance. Analysis of variance is essentially exactly the same model, with $x_1, x_2, \dots, x_q$ being

dummy variables coding factor levels and interactions between factors; analysis of covariance is also the same model with a mixture of continuous and categorical explanatory variables. (The equivalence of multiple regression to analysis of variance and so on is sometimes referred to as the *general linear model* – see, for example [3]).

The assumption of the conditional normality of a continuous response variable is one that is probably made more often than it is warranted. And there are many situations where such an assumption is clearly not justified. One example is where the response is a binary variable (e.g., improved, not improved), another is where it is a count (e.g., number of correct answers in some testing situation). The question then arises as to how the multiple regression model can be modified to allow such responses to be related to the explanatory variables of interest. In the GLM approach, the generalization of the multiple regression model consists of allowing the following three assumptions associated with this model to be modified.

- The response variable is normally distributed with a mean determined by the model.
- The mean can be modeled as a linear function of (possibly nonlinear transformations) the explanatory variables, that is, the effects of the explanatory variable on the mean are additive.
- The variance of the response variable given the (predicted) mean is constant.

In a GLM, some transformation of the mean is modeled by a linear function of the explanatory variables, and the distribution of the response around its mean (often referred to as the *error distribution*) is generalized usually in a way that fits naturally with a particular transformation. The result is a very wide class of regression models, but before detailing the unifying features of GLMs, it will be helpful to look at how a particular type of model, logistic regression, fits into the general framework.

Logistic Regression

Logistic regression is a technique widely used to study the relationship between a binary response and a set of explanatory variables. The expected value (μ) of a binary response is simply the probability, π , that the response variable takes the value one (usually

2 Generalized Linear Models (GLM)

used as the coding for the occurrence of the event of interest, say ‘improved’). Modeling this expected value directly as a linear function of explanatory variables, as is done in multiple linear regression, is now clearly not sensible since it could result in fitted values of the response variable outside the range (0, 1). And, in addition, the error distribution of the response, given the explanatory variables, will clearly not be normal. Consequently, the multiple regression model is adapted by first introducing a transformation of the expected value of the response, $g(\mu)$, and then using a more suitable error distribution. The transformation g is called a *link function* in GLM, and a suitable link function for a binary response is the logistic or logit giving the model

$$\text{logit}(\pi) = \log\left(\frac{\pi}{1-\pi}\right) = \beta_0 + \beta_1 x_1 + \cdots + \beta_q x_q. \quad (2)$$

As π varies from 0 to 1, the logit of π can vary from $-\infty$ to ∞ , so overcoming the first problem noted above. Now, we need to consider the appropriate error distribution. In linear regression, the observed value of the response variable is expressed as its expected value, given the explanatory variables plus an error term. With a binary response, we can express an observed value in the same way, that is:

$$y = \pi + \varepsilon, \quad (3)$$

but here, ε can only assume one of two possible values; if $y = 1$, then $\varepsilon = 1 - \pi$ with probability π , and if $y = 0$, then $\varepsilon = -\pi$ with probability $1 - \pi$. Consequently, ε has a distribution with mean zero and variance equal to $\pi(1 - \pi)$, that is, a binomial distribution for a single trial (also known as a Bernoulli distribution – see **Catalogue of Probability Density Functions**).

The Generalized Linear Model

Having seen the changes needed to the basic multiple linear regression model needed to accommodate a binary response variable, we can now see how the model is generalized in a GLM to accommodate a wide range of possible response variables with differing link functions and error distributions. The three essential components of a GLM are:

- A linear predictor, η , formed from the explanatory variables

$$\eta = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_q x_q. \quad (4)$$

- A transformation of the mean, μ , of the response variable called the link function, $g(\mu)$. In a GLM, it is $g(\mu)$ which is modeled by the linear predictor

$$g(\mu) = \eta. \quad (5)$$

In multiple linear regression and analysis of variance, the link function is the identity function. Other link functions include the log, logit, probit, inverse, and power transformations, although the log and logit are those most commonly met in practice. The logit link, for example, is the basis of logistic regression.

- The distribution of the response variable given its mean μ is assumed to be a distribution from the *exponential family*; this has the form

$$f(y; \theta, \phi) = \exp \left\{ \frac{(y\theta - b(\theta))}{a(\phi) + c(y, \phi)} \right\}. \quad (6)$$

For some specific functions, a , b , and c , and parameters θ and ϕ .

- For example, in linear regression, a normal distribution is assumed with mean μ and constant variance σ^2 . This can be expressed via the exponential family as follows:

$$\begin{aligned} f(y; \theta, \phi) &= \frac{1}{\sqrt{(2\pi\sigma^2)}} \exp \left\{ \frac{-(y - \mu)^2}{2\sigma^2} \right\} \\ &= \exp \left\{ \frac{(y\mu - \mu^2/2)}{\sigma^2} \right. \\ &\quad \left. - \frac{1}{2} \left(\frac{y^2}{\sigma^2} + \log(2\pi\sigma^2) \right) \right\} \end{aligned} \quad (7)$$

so that $\theta = \mu$, $b(\theta) = \theta^2/2$, $\phi = \sigma^2$ and $a(\phi) = \phi$. Other distributions in the exponential family include the binomial distribution, Poisson distribution, gamma distribution, and exponential distribution (see **Catalogue of Probability Density Functions**).

- Particular link function in GLMs are naturally associated with particular error distributions, for example, the identity link with the Gaussian distribution, the logit with the binomial, and the log with the Poisson. In these cases, the term *canonical link* is used.

The choice of probability distribution determines the relationships between the variance of the response variable (conditional on the explanatory variables) and its mean. This relationship is known as the *variance function*, denoted $\phi V(\mu)$. We shall say more about the variance function later.

Estimation of the parameters in a GLM is usually carried out through **maximum likelihood**. Details are given in [2, 6]. Having estimated the parameters, the question of the fit of the model for the sample data will need to be addressed. Clearly, a researcher needs to be satisfied that the chosen model describes the data adequately before drawing conclusions and making interpretations about the parameters themselves. In practice, most interest will lie in comparing the fit of competing models, particularly in the context of selecting subsets of explanatory variables so as to achieve a more parsimonious model. In GLMs, a measure of fit is provided by a quantity known as the *deviance*. This is essentially a statistic that measures how closely the model-based fitted values of the response approximate the observed values; the deviance quoted in most examples of GLM fitting is actually -2 times the maximized log-likelihood for a model, so that differences in deviances of competing models give a likelihood ratio test for comparing the models. A more detailed account of the assessment of fit for GLMs is given in [1].

An Example of Fitting a GLM

The data shown in Table 1 are given in [5] and also in [9]. They arise from asking randomly chosen household members from a probability sample of a town in the United States where stressful events had occurred within the last 18 months, and to report the month of occurrence of these events. A scatterplot of the data (see Figure 1) indicates a decline in the number of events as these lay further in the past, the result perhaps of the fallibility of human memory.

Since the response variable here is a count that can only take zero or positive values, it would not be appropriate to use multiple linear regression here to investigate the relationship of recalls to time. Instead, we shall apply a GLM with a log link function so that fitted values are constrained to be positive, and, as error distribution, use the Poisson distribution that is suitable for count data. These two assumptions lead to what is usually labelled *Poisson regression*.

Table 1 Distribution by months prior to interview of stressful events reported from subjects; 147 subjects reporting exactly one stressful event in the period from 1 to 18 months prior to interview. (Taken with permission from Haberman, 1978)

time	y
1	15
2	11
3	14
4	17
5	5
6	11
7	10
8	4

Explicitly, the model to be fitted to the mean number of recalls, μ , is:

$$\log(\mu) = \beta_0 + \beta_1 \text{time}. \quad (8)$$

The results of the fitting procedure are shown in Table 2.

The estimated regression coefficient for time is -0.084 with an estimated standard error of 0.017 . Exponentiating the equation above and inserting the

Table 2 Results of a Poisson regression on the data in Table 1.8

Covariates	Estimated regression coefficient	Standard error	Estimate/SE
(Intercept)	2.803	0.148	18.920
Time	−0.084	0.017	−4.987

(Dispersion Parameter for Poisson family taken to be 1).
Null Deviance: 50.84 on 17 degrees of freedom.
Residual Deviance: 24.57 on 16 degrees of freedom.

Figure 2 Recalled memories data showing fitted Poisson regression model

estimated parameter values gives the model in terms of the fitted counts rather than their logs, that is,

$$\hat{\mu} = 16.5 \times 0.920^{\text{time}}. \quad (9)$$

The scatterplot of the original data, now also showing the fitted model, is given in Figure 2. The difference in deviance of the null model and one including time as an explanatory variable is large and clearly indicates that the regression coefficient for time is not zero.

Overdispersion

An important aspect of generalized linear models that thus far we have largely ignored is the variance function, $V(\mu)$, that captures how the variance of a response variable depends upon its mean. The general form of the relationship is:

$$\text{Var}(\text{response}) = \phi V(\mu), \quad (10)$$

where ϕ is a constant and $V(\mu)$ specifies how the variance depends on the mean μ . For the error distributions considered previously, this general form becomes:

- (1) Normal: $V(\mu) = 1, \phi = \sigma^2$; here the variance does not depend on the mean and so can be freely estimated
- (2) Binomial: $V(\mu) = \mu(1 - \mu), \phi = 1$
- (3) Poisson: $V(\mu) = \mu; \phi = 1$

In the case of a Poisson variable, we see that the mean and variance are equal, and in the case of a binomial variable, where the mean is the probability of the occurrence of the event of interest, π , the variance is $\pi(1 - \pi)$. Both the Poisson and binomial distributions have variance functions that are completely determined by the mean. There is no free parameter for the variance since in applications of the generalized linear model with binomial or Poisson error distributions the dispersion parameter, ϕ , is defined to be one (see previous results for Poisson regression). But in some applications, this becomes too restrictive to fully account for the empirical variance in the data; in such cases, it is common to describe the phenomenon as *overdispersion*. For example, if the response variable is the proportion of family members who have been ill in the past year, observed in a large number of families, then the individual binary observations that make up the observed proportions are likely to be correlated rather than independent. This nonindependence can lead to a variance that is greater (less) than that on the assumption of binomial variability. And observed counts often exhibit larger variance than would be expected from the Poisson assumption, a fact noted by Greenwood and Yule over 80 years ago [4]. Greenwood and Yule's suggested solution to the problem was a model in which μ was a random variable with a γ distribution leading to a negative binomial distribution for the count (see **Catalogue of Probability Density Functions**).

There are a number of strategies for accommodating overdispersion but a relatively simple approach is one that retains the use of the binomial or Poisson error distributions as appropriate, but allows the estimation of a value of ϕ from the data rather than defining it to be unity for these distributions. The estimate is usually the residual deviance divided by its degrees of freedom, exactly

the method used with Gaussian models. Parameter estimates remain the same but parameter standard errors are increased by multiplying them by the square root of the estimated dispersion parameter. This process can be carried out manually, or almost equivalently, the overdispersed model can be formally fitted using a procedure known as *quasi-likelihood*; this allows estimation of model parameters without fully knowing the error distribution of the response variable – see [6] for full technical details of the approach.

When fitting generalized linear models with binomial or Poisson error distributions, overdispersion can often be spotted by comparing the residual deviance with its degrees of freedom. For a well-fitting model, the two quantities should be approximately equal. If the deviance is far greater than the degrees of freedom, overdispersion may be indicated.

An example of the occurrence of overdispersion when fitting a GLM with a log link and Poisson errors is reported in [8], for data consisting of the observation of number of days absent from school during the school-year amongst Australian Aboriginal and white children. The explanatory variables of interest in this study were gender, age, type (average or slow learner), and ethnic group (Aboriginal or White). Fitting the usual Poisson regression model resulted in a deviance of 1768 with 141 degrees of freedom, a clear indication of overdispersion. In this model, both gender and type were indicated as being highly significant predictors of number of days absent. But when overdispersion was allowed for in the way described above, both these variables became nonsignificant. A possible reason for overdispersion in these data is the substantial variability in children's tendency to miss days of school that cannot be fully explained by the variables that have been included in the model.

Summary

Generalized linear models provide a very powerful and flexible framework for the application of

regression models to medical data. Some familiarity with the basis of such models might allow medical researchers to consider more realistic models for their data rather than to rely solely on linear and logistic regression.

Genotype

The genotype of an organism is its genes, or genetic make-up, as opposed to its phenotype, or outward appearance. The physical basis of the human genotype lies in 23 pairs of chromosomes – microscopic bodies present in every cell nucleus. One pair is the sex chromosomes, and the other 22 pairs are known as autosomes, or autosomal chromosomes. The two alleles at each locus on the autosomes comprise the genotype for that locus. If the two alleles are the same, the genotype is called *homozygous*; if they are different, the genotype is called *heterozygous*. Persons with homozygous and heterozygous genotypes are called *homozygotes* and *heterozygotes* respectively.

If the phenotype, or phenotypic distribution, associated with a particular heterozygote is the same as that associated with one of the two corresponding homozygotes, then the allele in that homozygote is **dominant**, and the allele in the other corresponding homozygote is recessive, with respect to the phenotype; the locus is said to exhibit dominance (*see Allelic Association*). If the heterozygote expresses a phenotype that has features of both corresponding homozygotes, – for example, persons with AB blood type have both A and B antigens on their red

cells, determined by A and B alleles at the ABO locus – then there is said to be codominance. At the DNA level, that is, if the phenotype associated with a genotype is the DNA constitution itself, then all loci exhibit codominance.

The genotype being considered may involve the alleles at more than one locus. However, a distinction should be made between the genotype at multiple loci and the multilocus genotype. Whereas the former is specified by all the alleles at the loci involved, the latter is specified by the two haplotypes a person inherited, that is, the separate sets of maternal alleles and paternal alleles at the various loci.

In the case of a quantitative trait, there is a dominance component to the variance if the heterozygote phenotype is not half-way between the two corresponding homozygote phenotypes, that is, if the phenotypic effects of the alleles at a locus are not additive. Similarly, if the phenotypic effect of a multilocus genotype is not the sum of the constituent one-locus genotypes, then there is **epistasis**. Dominance can be thought of as intralocus interaction and epistasis as interlocus interaction. Thus, in the case of a quantitative phenotype, the presence or absence of dominance and/or epistasis depends on the scale of measurement of the phenotype.

Geometric Mean

The geometric mean $\bar{X}_g$ of a set of n numbers $X_1, X_2, \dots, X_n (i = 1, 2, \dots, n)$ is defined as

$$\bar{X}_g = (X_1 \times X_2 \times \dots \times X_n)^{\frac{1}{n}} \quad (1)$$

The geometric mean is only defined for a set of positive numbers.

As an example, we see that the geometric mean of 10 and 15 is

$$\begin{aligned} \bar{X}_g &= (10 \times 15)^{\frac{1}{2}} = \sqrt{150} \\ &= 12.25 \text{ (to 2 decimal places).} \end{aligned} \quad (2)$$

The geometric mean has an advantage over the arithmetic mean in that it is less affected by very small or very large values in skewed data. For instance, the arithmetic mean of the scores 10, 15, and 150 is 58.33, whereas the geometric mean for the same figures is 28.23.

An additional use of the geometric mean is when dealing with numbers that are ratios of other numbers, such as percentage increase in weight. Imagine that we want the mean percentage weight gain for the data in Table 1, which shows a person's weight at the end of each year, expressed as a percentage of the previous year.

Table 1 Weight at the end of each year, expressed as a percentage of the previous year

Year	Percentage
1	104
2	107
3	109
4	113

The arithmetic mean of the percentages is 108.25, while the geometric mean is 108.20. Now, if we had been told that a person started year 1 with a weight of 50 kg, then that person's weight after each of the four years would be 52, 55.64, 60.65, and 68.53 kg, respectively. If the arithmetic mean were used to calculate the weights, it would give the person's weight for the four years as 54.13, 58.59, 63.42, and 68.66 kg, while if the geometric mean were used it would give the person's weight for the four years as 54.10, 58.54, 63.34, and 68.53 kg. Thus, although the geometric mean has produced figures for the intermediate years that are not totally accurate, unlike the arithmetic mean it produces the correct figure for the final value. Accordingly, it would be more precise to say that the person had an average weight gain of 8.2% than to say it was 8.25%.

Goodness of Fit

Goodness-of-fit indices (GFI) are indices used in **structural equation modeling** and with other mathematical models to assess the fit of a model to data. They should be interpreted in terms of the overidentifying constraints placed on the model, for only these produce lack of fit. They are of two kinds: (a) exact fit indices and (b) approximate fit indices.

Exact fit indices are used with a sampling distribution to test the hypothesis that the model fits the population data exactly. Thus, before using an exact fit test, the researcher should have good reasons that the sampling distribution to be used in statistical inference applies to the data in question. Exact fit indices only test whether or not the hypothesized model fits the data to within sampling error. Fitting to within sampling error does not mean that the model is true. Other ‘equivalent models’ may be equally formulated to fit the data to within sampling error. Failure to fit to within sampling error only means that the data is so different and so improbable under the assumption of the truth of the hypothesis as to make the hypothesis difficult to believe. With failure to fit, one should seek to determine the sources of lack of fit, using program diagnostics and a review of theory and the content of the variables. However, failure to fit does not imply that every feature of the model is incorrect. It merely indicates that at least one feature *may* be incorrect, but it does not indicate which.

When the model fits to within sampling error, one may act as if the model is provisionally correct, but should be prepared for the possibility that at a later date further studies may overturn the model. Exact fit tests also increase in power to reject the hypothesized model with ever larger samples. Most multivariate models require large samples to justify the theoretical sampling distributions used with exact fit indices. So, just as it becomes reasonable to use these distributions in probabilistic inference, the power of these tests may make it possible to detect miniscule, if not practically negligible, discrepancies between the mathematical model hypothesized and the data, leading to rejection of the model. This, and the fact that many data sets do not satisfy exactly the distributional assumptions of the exact fit test, has been the basis for many researchers’ use of approximate fit indices to judge the quality of their models by their degree of approximation to the data.

Approximate fit indices indicate the degree to which the model fits the data. Some approximate fit indices use indices that range between 0 (total lack of fit) and 1 (perfect fit). Other approximate fit indices measure the distance between the data and the model, with 0 perfect fit, and infinity indicating total lack of fit. Usually, approximate fit indices are used with some criterion value close to perfect fit to indicate whether the model is a good approximation or not. However, it must always be recognized that an approximation is always *that* and not indicative of the incorrigible correctness of the model. Getting good approximations is indicative that a preponderance of the evidence supports the essential features of the model. But, further research with the model should also include a search for the reasons for lack of exact fit.

Let $\mathbf{U}$ and $\mathbf{V}$ be two $p \times p$ covariance matrices, with $\mathbf{U}$ a less restricted variance–covariance matrix representing the data and $\mathbf{V}$ a more constrained variance–covariance matrix hypothesized for the data. Browne [2] noted that most structural equation models are fit to data using discrepancy functions, which are scalar valued-functions $F(\mathbf{U}; \mathbf{V})$ with the following properties: (a) $F(\mathbf{U}; \mathbf{V}) \geq 0$. (b) $F(\mathbf{U}; \mathbf{V}) = 0$ if and only if $\mathbf{U}$ and $\mathbf{V}$ are equal. (c) $F(\mathbf{U}; \mathbf{V})$ is continuous in both $\mathbf{U}$ and $\mathbf{V}$.

There are a number of standard discrepancy functions, like unweighted least squares, weighted least squares (*see Least Squares Estimation*) and maximum likelihood’s fit function (*see Maximum Likelihood Estimation*) that are used in estimating unknown parameters of models conditional on constraints on specified model parameters. For example, the least-squares discrepancy function is

$$F_{LS} = \text{tr}[(\mathbf{U} - \mathbf{V})(\mathbf{U} - \mathbf{V})], \quad (1)$$

and the maximum likelihood’s fit function

$$F_{ML} = \ln|\mathbf{V}| - \ln|\mathbf{U}| - \text{tr}(\mathbf{U}\mathbf{V}^{-1}) - p \quad (2)$$

is also a discrepancy function. In fact, the chi-squared statistic $\chi_{df}^2 = (N - 1)F_{ML}$ is also a discrepancy function.

Cudeck and Henley [4] defined three sources of error in model fitting. First, let $\mathbf{S}$ be a $p \times p$ sample variance–covariance matrix for p observed variables to be used as the data to which a structural equation model is fit. Let Σ be the variance/covariance matrix of the population from which the sample

2 Goodness of Fit

variance/covariance matrix $\mathbf{S}$ has been drawn. Next, define $\hat{\Sigma}_0$ to be the maximum likelihood (ML) estimate of a model with free, fixed, and constrained parameters fit to $\mathbf{S}$. The error of fit given by the discrepancy function value $F(\mathbf{S}; \hat{\Sigma}_0)$ contains both sampling error and error of approximation of the model to the population covariance matrix. Analogously, let $\tilde{\Sigma}_0$ be the estimate of the same model fit to the population variance–covariance matrix Σ . The error of fit in this case is $F(\Sigma; \tilde{\Sigma}_0)$ and is known as the *error of approximation*. It contains no sampling error. It is a population parameter of lack of fit of the model to the data. It is never measured directly and is only inferred from the data. $F(\tilde{\Sigma}_0; \hat{\Sigma}_0)$ is known as the *error of estimation*, the discrepancy between sample estimate and population estimate for the model.

The chi-squared statistic of an exact fit test is given as

$$\chi_{df}^2 = (N-1)F(\mathbf{S}; \hat{\Sigma}_0) = (N-1) \times \left[\ln|\hat{\Sigma}_0| - \ln|\mathbf{S}| + \text{tr}(\hat{\Sigma}_0^{-1}\mathbf{S}) - p \right]. \quad (3)$$

$F(\mathbf{S}; \hat{\Sigma}_0)$ is the minimum value of the discrepancy function when the maximum likelihood estimates are optimized.

Assuming the variables have a joint multivariate normal distribution (see **Catalogue of Probability Density Functions**), this statistic is used to test the hypothesis that the constrained model covariance matrix is the population covariance matrix that generated the sample covariance matrix $\mathbf{S}$. One rejects the null hypothesis that the model under the constraints generated $\mathbf{S}$, when $\chi_{df}^2 > c$, where c is some constant such that $P(\chi_{df}^2 > c | H_0 \text{ is true}) \leq \alpha$. Here α is the probability one accepts of making a Type I error.

In many cases, the model fails to fit the data. In this case, chi squared does not have an approximate chi-squared distribution, but a noncentral chi-squared distribution, whose expectation is

$$E(\chi_{df}^2) = df + \delta^{*2}, \quad (4)$$

where df are the degrees of freedom of the model and δ^{*2} , the noncentrality parameter for the model. The noncentrality parameter is a measure of the lack of fit of the model for samples of size N . Thus, an unbiased estimate of the noncentrality parameter is given by

$$\hat{\delta}^{*2} = \chi_{df}^2 - df. \quad (5)$$

McDonald [8] recommended that instead of using this as a fundamental index of lack of fit, one should normalize this estimate by dividing it by $(N-1)$ to control for the effect of sample size. Thus, the normalized noncentrality estimate is given by

$$\hat{\delta} = \frac{\hat{\delta}^{*2}}{(N-1)} = \frac{\chi_{df}^2 - df}{(N-1)} = F_{ML} - \frac{df}{(N-1)}. \quad (6)$$

The population raw noncentrality δ^{*2} and the population normalized noncentrality δ are related as $\delta^{*2} = (N-1)\delta$. As N increases without bound, and $\delta > 0$, the noncentrality parameter is undefined in the limit.

Browne and Cudeck [3] argue that $\hat{\delta}$ is a less biased estimator of the normalized population discrepancy $\delta = F(\Sigma; \tilde{\Sigma}_0)$ than is the raw $F_{ML} = F(\mathbf{S}; \hat{\Sigma}_0) = \chi_{df}^2/(N-1)$, which has for its expectation

$$E(F_{ML}) = F(\Sigma; \tilde{\Sigma}_0) + \frac{df}{(N-1)}. \quad (7)$$

In fact,

$$\begin{aligned} E(\hat{\delta}) &= E(F_{ML}) - \frac{df}{(N-1)} = E(F_{ML}) \\ &\quad + \frac{df - df}{(N-1)} = F(\Sigma; \tilde{\Sigma}_0) = \delta. \end{aligned} \quad (8)$$

So, the estimated normalized noncentrality parameter is an unbiased estimate of the population normalized discrepancy.

Several indices of approximation are based on the noncentrality and normalized noncentrality parameters.

Bentler [1] and McDonald and Marsh [9] simultaneously defined an index given the name FI by Bentler:

$$\begin{aligned} FI &= \frac{(\hat{\delta}_{\text{null}}^* - \hat{\delta}_k^*)}{\hat{\delta}_{\text{null}}^*} = \frac{[(\chi_{\text{null}}^2 - df_{\text{null}}) - (\chi_k^2 - df_k)]}{(\chi_{\text{null}}^2 - df_{\text{null}})} \\ &= \frac{\hat{\delta}_{\text{null}} - \hat{\delta}_k}{\hat{\delta}_{\text{null}}}. \end{aligned} \quad (9)$$

χ_{null}^2 is the chi squared of a ‘null’ model in which one hypothesizes that the population covariance matrix is a diagonal matrix with zero off-diagonal elements and free diagonal elements. Each nonzero covariance between any pair of variables in the data will produce a lack of fit for the corresponding zero covariance in this model. Hence, lack of fit δ_{null} of this model

can serve as an extreme norm against which to compare the lack of fit of model k , which is actually hypothesized. The difference in lack of fit between the null model and model k is compared to the lack of fit of the null model itself. The result on the right is obtained by dividing the numerator and the denominator by $(N - 1)$. The index depends on unbiased estimates and is itself relatively free of bias at different sample sizes. Bentler [1] further corrected the FI index to be 0 when it became occasionally negative and to be 1 when it occasionally exceeded 1. He called the resulting index the CFI (comparative fit index). A common rule of thumb is that models with $CFI \geq .95$ are ‘acceptable’ approximations.

Another approximation index first recommended by Steiger and Lind [10] but popularized by Browne and Cudeck [3] is the RMSEA (root mean squared error of approximation) index, given by

$$\begin{aligned} RMSEA &= \sqrt{\text{Max.} \left\{ \left(\frac{\chi^2_{df_k} - df_k}{(N - 1)df_k} \right), 0 \right\}} \\ &= \sqrt{\text{Max.} \left\{ \left(\frac{\hat{\delta}_k}{df_k} \right), 0 \right\}}. \end{aligned} \quad (10)$$

This represents the square root of the estimated normalized noncentrality of the model divided by the model’s degrees of freedom. In other words, it is the average normalized noncentrality per degree of freedom. Although some have asserted that this represents the noncentrality adjusted for model parsimony, this is not the case. A model may introduce constraints and be more parsimonious with more degrees of freedom, and the average discrepancy per additional degree of freedom may not change. The RMSEA index ranges between 0 (perfect fit) and infinity. A value of $RMSEA \leq .05$ is considered to be ‘acceptable’ approximate fit. Browne and Cudeck [3] indicate that a confidence interval estimate for the RMSEA is available to indicate the precision of the RMSEA estimate.

Another popular index first popularized by Jöreskog and Sörbom’s LISREL program [7] (see **Structural Equation Modeling: Software**) is inspired by Fisher’s intraclass correlation [5]:

$$R^2 = 1 - \frac{\text{Error Variance}}{\text{Total Variance}}. \quad (11)$$

The GFI index computes ‘error’ as the sum of (weighted and possibly transformed) squared differences between the elements of the observed variance/covariance matrix $\mathbf{S}$ and those of the estimated model variance/covariance matrix $\hat{\Sigma}_0$ and compares this sum to the total sum of squares of the elements in $\mathbf{S}$. The matrix $(\mathbf{S} - \hat{\Sigma}_0)$ is symmetric and produces the element-by-element differences between $\mathbf{S}$ and $\hat{\Sigma}_0$. $\mathbf{W}$ is a transformation matrix that weights and combines the elements of these matrices, depending on the method of estimation. Thus, we have

$$GFI = 1 - \frac{\text{tr}[\mathbf{W}^{-1/2}(\mathbf{S} - \hat{\Sigma}_0)\mathbf{W}^{-1/2}]^2}{\text{tr}[\mathbf{W}^{-1/2}(\mathbf{S})\mathbf{W}^{-1/2}][\mathbf{W}^{-1/2}(\mathbf{S})\mathbf{W}^{-1/2}]}, \quad (12)$$

where

$\hat{\Sigma}_0$ is the model variance/covariance matrix and $\mathbf{S}$ is the unrestricted, sample variance/covariance matrix and

$$\mathbf{W} = \begin{cases} \mathbf{I} - \text{Unweighted Least Squares} \\ \mathbf{S} - \text{Weighted Least Squares} \\ \hat{\Sigma}_0 - \text{Maximum Likelihood} \end{cases}. \quad (13)$$

For maximum likelihood estimation the GFI simplifies to

$$GFI_{ML} = 1 - \frac{\text{tr}[(\mathbf{S}\hat{\Sigma}_0^{-1} - \mathbf{I})(\mathbf{S}\hat{\Sigma}_0^{-1} - \mathbf{I})]}{\text{tr}(\mathbf{S}\hat{\Sigma}_0^{-1}\mathbf{S}\hat{\Sigma}_0^{-1})}. \quad (14)$$

A rule of thumb is again to consider a $GFI > 0.95$ to be an ‘acceptable’ approximation. Hu and Bentler [6] found that the GFI tended to underestimate its asymptotic value in small samples, especially when the latent variables were interdependent. Furthermore, the maximum likelihood (ML) and generalized least squares (GLS) variants of the index performed poorly in samples less than 250.

Steiger [11] has suggested a variant of the GFI such that under a general condition where the model is invariant under a constant scaling function the GFI has a known population parameter

$$\Gamma_1 = \frac{p}{2F_{ML}(\Sigma; \tilde{\Sigma}_0) + p} \quad (15)$$

to estimate. Note that as $F(\Sigma; \tilde{\Sigma}_0)$ becomes close to zero, this index approaches unity, whereas when $F(\Sigma; \tilde{\Sigma}_0)$ is greater than zero and increasing, this

4 Goodness of Fit

parameter declines toward zero, with its becoming zero when $F(\Sigma; \hat{\Sigma}_0)$ is infinitely large. Steiger shows that

$$\hat{\Gamma}_1 = \frac{p}{2F_{ML}(\mathbf{S}; \hat{\Sigma}_0) + p} \quad (16)$$

is equivalent to the GFI_{ML} and an estimate of Γ_1 . But it is a biased estimate, for the expectation of $\hat{\Gamma}_1$ is approximately

$$E(\hat{\Gamma}_1) \approx \frac{p}{2F_{ML}(\Sigma; \hat{\Sigma}_0) + 2df/(N-1) + p}. \quad (17)$$

The bias leads $\hat{\Gamma}_1$ to underestimate Γ_1 , but the bias diminishes as sample size N becomes large relative to the degrees of freedom of the model. Steiger [11] and Browne and Cudeck [3] report a confidence interval estimate using $\hat{\Gamma}_1$ that may be used to test hypotheses about Γ_1 .

There are numerous other indices of approximate fit, but those described here are the most popular.

Goodness of fit should not be the only criterion for evaluating a model. Models with zero degrees of freedom always fit perfectly as a mathematical necessity and, thus, are useless for testing hypotheses. Besides having acceptable fit, the model should be parsimonious in having numerous degrees of freedom relative to the number of nonredundant elements in the variance-covariance matrix, and should be realistic in representing processes in the phenomenon modeled.

Goodness of Fit for Categorical Variables

Introduction

The explanation of the frequency distributions of categorical variables often involves the specification of probabilistic models. The appropriateness of these models can be examined using *goodness-of-fit statistics*. A goodness-of-fit statistic assesses the distance between the data and the model. This characteristic is the reason why goodness-of-fit statistics are often also called *badness-of-fit statistics*. Under the null hypothesis that this distance is random, the probability is then estimated that the observed data or data with even larger distances are obtained. This probability is called the *size of the test*.

Goodness-of-fit is examined at two levels. The first is the aggregate level. At this level, one asks whether a probability model describes the data well, overall. The second is the level of individual cells or groups of cells. At this level, one asks whether the distances in individual cells or groups of cells are greater than compatible with the assumption of random deviations. Cells that display particularly strong deviations have been called *outlier cells*, *extreme cells*, *outlandish cells* [14], *rogue cells* [15], *aberrant cells*, *anomalous cells* [21], and *types and antitypes* [10, 16].

A large number of tests has been proposed to examine goodness-of-fit, and performance and characteristics of these tests differ greatly (comparisons were presented, e.g., by [16–18]). In the following paragraphs, we discuss goodness-of-fit tests from two perspectives. First, we present the tests and describe them from the perspective of *overall goodness-of-fit*, that is, from the perspective of whether a probability model as a whole explains the data well. Second, we discuss tests and their performance when applied to individual cells. In both sections, we focus on count data and on multinomial sampling.

Testing Overall Goodness-of-fit

A most general indicator of goodness-of-fit is Cressie and Read's [3, 13] *power divergence statistic*,

$$I(\lambda) = \frac{2}{\lambda(\lambda + 1)} \sum_i n_i \left[\left(\frac{n_i}{m_i} \right)^\lambda - 1 \right], \quad (1)$$

where

λ = real-valued parameter, with $-\infty < \lambda < \infty$,

i = index that goes over all cells of a table,

n_i = observed frequency of Cell i , and

m_i = expected frequency of Cell i .

This statistic is important because it can, by way of selecting particular scores of λ , be shown to be identical to other well-known measures of goodness-of-fit (see [1]). Specifically,

- (1) for $\lambda = 1$, I is equal to Pearson's X^2 ; one obtains

$$I(1) = X^2 = \sum \frac{(n_i - m_i)^2}{m_i}; \quad (2)$$

- (2) as $\lambda \rightarrow 0$, I converges to the likelihood ratio G^2 ,

$$I(\lambda \rightarrow 0) \rightarrow G^2 = 2 \sum_i n_i \log \left(\frac{n_i}{m_i} \right); \quad (3)$$

- (3) as $\lambda \rightarrow -1$, I converges to Kullback's [7] *minimum discrimination information statistic*,

$$I(\lambda \rightarrow -1) \rightarrow GM \rightarrow 2 \sum_i m_i \log \left(\frac{n_i}{m_i} \right); \quad (4)$$

- (4) for $\lambda = -2$, I is equal to Neyman's [12] *modified chi-squared statistic*,

$$I(\lambda = -2) = NM^2 = \sum_i \frac{(n_i - m_i)^2}{n_i}; \quad (5)$$

and

- (5) for $\lambda = -0.5$, I is equal to Freeman and Tukey's [4] statistic

$$I\left(\frac{1}{2}\right) = FT = 4 \sum_i (\sqrt{n_i} - \sqrt{m_i})^2. \quad (6)$$

Under regularity conditions, these six statistics are asymptotically identically distributed. Specifically, these statistics are asymptotically distributed as χ^2 , with $df = I - 1$, where I is the number of cells. However, the value of $\lambda = 2/3$ has shown to be

2 Goodness of Fit for Categorical Variables

superior to other values of λ . It leads to a statistic that keeps the α level better, and has better small sample power characteristics.

Comparisons of the two best known of these six statistics, the Pearson X^2 and the likelihood ratio X^2 (see **Contingency Tables**), have shown that the Pearson statistic is often closer to the χ^2 distribution than G^2 . However, G^2 has better decomposition characteristics than X^2 . Therefore, decompositions of the effects in cross-classifications (see **Chi-Square Decomposition**) and comparisons of hierarchically related **log-linear models** are typically performed using the G^2 statistic.

There exists a number of other goodness-of-fit tests. These include, for instance, the Kolmogorov–Smirnov test, the Cramer-von Mises test, and runs tests.

Testing Cellwise Goodness-of-fit

Testing goodness-of-fit for individual cells has been proposed for at least three reasons. First, the distribution of residuals in cross-classifications that are evaluated using particular probability models can be very uneven such that the residuals are large for a small number of cells and rather small for the remaining cells. Attempts at improving model fit then focus on reducing the discrepancies in the cells with the large residuals. Second, cells with large residuals can be singled out and declared structural frequencies, that is, *fixed*, and not taken into account when the expected frequencies are estimated. Typically, model fit improves considerably when outlandish cells are fixed. Third, cell-specific goodness-of-fit indicators are examined with the goal of finding types and antitypes in **configural frequency analysis** see von Eye in this encyclopedia, [10, 16, 17]. Types and antitypes are then interpreted with respect to the probability model that was used to explain a cross-classification. Different probability models can yield different patterns of types and antitypes. In either context, decisions are made concerning single cells or groups of cells.

The most popular measures of cellwise lack of fit include the *raw residual*, the *Pearson residual*, the *standardized Pearson residual*, and the *adjusted residual*. The raw residual is defined as the difference between the observed and the expected cell frequencies, that is, $n_i - m_i$. This measure indicates

the number of cases by which the observed frequency distribution and the probability model differ in Cell i . The Pearson residual for Cell i is the i th summand of the overall X^2 given above.

For the standardized Pearson residual, one can find different definitions in the literature. According to Agresti [1], for Cell i which has an estimated leverage of $\hat{h}_i$, the standardized Pearson residual is

$$r_i = \frac{n_i - m_i}{\sqrt{m_i \left(1 - \frac{n_i}{N}\right) (1 - \hat{h}_i)}}, \quad (7)$$

where $\hat{h}_i$ is defined as the diagonal element of the *hat* matrix (for more detail on the hat matrix see [11]). The absolute value of the standardized Pearson residual is slightly larger than the square root of the Pearson residual (which is often called the standardized residual; see [8]), and it is approximately normally distributed if the model holds.

The *adjusted residual* [5] is a standardized residual that is divided by its standard deviation. Adjusted residuals are typically closer to the normal distribution than $\sqrt{X^2}$. *Deviance residuals* are the components of the likelihood ratio statistic, G^2 , given above. Exact residual tests can be performed using, for instance, the binomial test and the hypergeometric test. The latter requires product-multinomial sampling (see **Sampling Issues in Categorical Data**).

The characteristics and performance of these and other residual tests have been examined in a number of studies (e.g., [6, 9, 17, 19, 20]). The following list presents a selection of repeatedly reported results of comparison studies.

1. The distribution of the adjusted residual is closer to the normal distribution than that of the standardized residual.
2. Both the approximative and the **exact tests** tend to be conservative when the expected cell frequencies are estimated from the sample marginals.
3. As long as cell frequencies are small (less than about $n_i = 100$), the distribution of residuals tends to be asymmetric such that positive residuals are more likely than negative residuals; for larger cell sizes, this ratio is inverted; this applies to tables of all sizes greater than 2×2 and under multinomial as well as product-multinomial sampling.

4. The α -curves of the residuals suggest conservative decisions as long as cell sizes are small.
5. The β curves of the residuals also suggest that large sample sizes are needed to make sure the β -error is not severely inflated; this applies to tables of varying sizes, to both multinomial and product-multinomial sampling, as well as to the α -levels of 0.05 and 0.01.
6. None of the tests presented here and the other tests that were also included in some of the comparison studies consistently outperformed all others; that is, the tests are differentially sensitive to characteristics of data and tables.

Data Example

The following data example presents a reanalysis of data from a project on the mental health outcomes of women experiencing domestic violence [2]. For the example, we attempt to predict Anxiety (A) from Poverty (Po), Psychological Abuse (Ps), and Physical Abuse (Ph). Anxiety and Poverty were dichotomized at the median, and Psychological and Physical Abuse were dichotomized at the score of 0.7 (to separate the no abuse cases from the abuse cases). For each variable, a 1 indicates a low score, and a 2 indicates a high score.

To test the prediction hypotheses, we estimated the hierarchical log-linear model [A, Po], [A, Ps], [A, Ph], [Po, Ps, Ph]. This model is equivalent to the **logistic regression model** that predicts A from Po, Ps, and Ph. The cross-tabulation of the four variables, including the observed and the estimated expected cell frequencies, appears in Table 1.

Table 1 suggests that the observed cell frequencies are relatively close to the estimated expected cell frequencies. Indeed, the overall goodness-of-fit likelihood ratio $X^2 = 3.50$ ($df = 4$; $p = 0.35$) indicates no significant model-data discrepancies. The Pearson $X^2 = 4.40$ ($df = 4$; $p = 0.48$) leads one to the same conclusion. The values of these two overall goodness-of-fit measures are the same if a model is the true one. In the present case, the values of the test statistics are not exactly the same, but since they are both small and suggest the same statistical decision, there is no reason to alter the model. Substantively, we find that the two abuse variables are significant predictors of Anxiety. In contrast, Poverty fails to make a significant contribution.

Table 1 Prediction of anxiety from poverty, psychological violence, and physical violence

Variable patterns				Frequencies	
A	Po	Ps	Ph	Observed	Expected
1	1	1	1	6	6.93
1	1	1	2	3	2.07
1	1	2	1	13	11.64
1	1	2	2	13	14.36
1	2	1	1	2	1.11
1	2	1	2	0	0.89
1	2	2	1	1	2.32
1	2	2	2	9	7.68
2	1	1	1	4	3.96
2	1	1	2	1	1.04
2	1	2	1	11	11.47
2	1	2	2	13	12.53
2	2	1	1	0	0.00
2	2	1	2	0	0.00
2	2	2	1	5	4.57
2	2	2	2	13	13.43

Table 2 presents the raw, the adjusted, the deviance, the Pearson, and the Freeman–Tukey residuals for the above model.

In the following paragraphs, we discuss four characteristics of the residuals in Table 2. First, the various residual measures indicate that no cell qualifies as extreme. None of the residuals that are distributed either normally or as χ^2 has values that would indicate that a cell deviates from the model (to make this statement, we use the customary thresholds of 2 for normally distributed residuals and 4 for χ^2 -distributed residuals). Before retaining a model, researchers can do worse than inspecting residuals for local model-data deviations.

Second, the Pearson X^2 is the only one that does not indicate the direction of the deviation. From inspecting the Pearson residual alone, one cannot determine whether an observed frequency is larger or smaller than the corresponding estimated expected one.

Third, the correlations among the four arrays of residuals vary within a narrow range, thus indicating that the measures are sensitive largely to the same characteristics of model-data discrepancies. Table 3 displays the correlation matrix.

The correlations in Table 3 are generally very high. Only the correlations with Pearson's measure are low. The reason for this is that the Pearson scores are positive by definition. Selecting only the positive

4 Goodness of Fit for Categorical Variables

Table 2 Residuals from the prediction model in Table 1

Variable patterns				Residuals

2	2	2	2	−0.43	−0.43	−0.92	0.01	−0.05

Table 3 Intercorrelations of the residuals in Table 2

	Raw	Adjusted	Deviance	Pearson
Adjusted	0.992	1.000		
Deviance	0.978	0.975	1.000	
Pearson	0.249	0.314	0.297	1.000
Freeman–Tukey	0.946	0.971	0.940	0.344

less than 1. The deviance residual has a standard deviation greater than one. This is an unusual result and may be specific to the data used for the present example. In general, the deviance residual is less variable than $N(0, 1)$, but it can be standardized.

Gosset, William Sealy

Born: June 13, 1876, in Canterbury, England.

Died: October 16, 1937, in Beaconsfield, England.

William Sealy Gosset studied at Winchester College before enrolling at New College, Oxford, where he earned a first class in mathematical moderations (1887) and another in natural sciences, specializing in chemistry (1899). Also, in 1899, and in conjunction with the company's plan to hire university-trained scientists, Arthur Guinness, Son & Co, brewers in Dublin, hired Gosset. Thus began Gosset's career, one that culminated with his appointment in 1935 as head of Guinness's newly constructed brewery in London, a position he held until his death. '...all his most important statistical work was undertaken in order to throw light on problems which arose in the analysis of data connected in some way with the brewery' [2, p. 212]. Gosset was, perhaps, the first and the most important industrial statistician [4].

After familiarizing himself with the operations of the brewery, where he had access to data bearing on brewing methods as well as the production and combinations of the hops and barley used in brewing, Gosset realized the potential value of applying error theory to such data. His first report (November 3, 1904) titled, 'The Application of the "Law of Error" to the work of the Brewery', presented the case for introducing statistical methods to the industry's work. Gosset also observed, 'We have met with the difficulty that none of our books mentions the odds, which are conveniently accepted as being sufficient to establish any conclusion, and it might be of assistance to us to consult some mathematical physicist on the matter' [2, p. 215].

Instead, Gosset contacted **Karl Pearson** (1905), which led to Gosset's studies (1906–1907) with Pearson and W. F. R. Weldon in the Biometric School of the University College, London. Following Francis Galton's lead, Pearson and Weldon were keen on refining measures of variation and correlation, primarily for agricultural and biological purposes, and to do so, they relied on large statistical samples. Gosset had earlier noted that 'correlation coefficients are usually calculated from large numbers of cases, in fact I have found only one paper in

Biometrika of which the cases are as few in number as those at which I have been working lately' (quoted in [2, p. 217].

Thus, it fell to Gosset, who typically had much smaller samples from the brewery's work available to him, to adapt the large-sample statistical methods to small samples. To develop small-sample methods, he drew small samples from some of Pearson et al.'s large samples, and in so doing Gosset provided '...the first instance in statistical research of the random sampling experiment...' [2, p. 223].

Guinness had a policy of not publishing the results of company research, but Gosset was permitted to publish his research on statistical methods using the pseudonym, 'Student'. Student's article, 'The Probable Error of a Mean' (*Biometrika*, 1908), a classic in statistics, introduced the *t* Test for small-sample statistics, and it laid much of the groundwork for **Fisher's** development of **analysis of variance** ([5, p. 167–168]; and see [3]).

Two informative articles about Gosset are "Student" as a statistician' [2] and "Student" as a man' [1]. Of Student as a statistician, Pearson concluded: '[Gosset's]... investigation published in 1908 has done more than any other single paper to bring [chemical, biological, and agricultural] subjects within the range of statistical inquiry; as it stands it has provided an essential tool for the practical worker, while on the theoretical side it has proved to contain the seed of ideas which have since grown and multiplied in hundredfold' [2, p. 224]. Of Student as a man, McMullen [1], described Gosset as being a golfer and a builder and sailor of boats of unusual design, made by preference using simple tools. He was also an accomplished fly fisherman. 'In fishing he was an efficient performer; he used to hold that only the size and general lightness or darkness of a fly were important; the blue wings, red tail, and so on being only to attract the fisherman to the shop' [1 p. 209].

Graphical Chain Models

Graphical Markov models represent relations, most frequently among random variables, by combining simple, yet powerful, concepts: data generating processes, graphs, and conditional independence. The origins can be traced back to independent work in genetics ([30]), in physics ([10]), and in probability theory (**A. A. Markov**, 1912, [20]). Wright used directed graphs to describe processes of how his genetic data could have been generated, and to check the consistency of such hypotheses with observed data. He called his method **path analysis**. Gibbs described total energy of systems of particles by the number of nearest neighbors for nodes in undirected graphs. Markov suggested how some seemingly complex structures can sometimes be explained in terms of a chain of simple dependencies using the notion of **conditional independence** (see **Markov Chains**).

Development of these ideas continued largely independently in mathematics, physics, and engineering. In the social sciences and econometrics, an extension of path analysis was developed, called *simultaneous equation models*, which does not directly utilize the notion of conditional independence, and which does not incorporate nonlinear relations or time-dependent variation. In decision analysis, computer science, and philosophy, extensions of path analysis have been called *influence diagrams*, belief networks, or **Bayesian networks**, and are used, among others, for constructing so-called expert systems and systems with learning mechanisms.

A systematic development of graphical Markov models for representing multivariate statistical dependencies for both discrete and continuous variables started in the 1970s, with work on fully undirected graph models for purely discrete and for Gaussian random variables, and on linear models with graphs that are fully directed and have no cycles. This work was extended to models permitting sequences of response variables to be considered on equal footing, that is, without specifications of a direction of dependence. Joint responses can be modeled in quite different ways, some define independence structures of distinct types of graphical chain model. Properties of corresponding types of graph have been studied intensively, so that, in particular, all independencies,

implied by a given graph, can be derived by so-called separation criteria.

Several books give overviews of theory, analyses, and interpretations of graphical Markov models in statistics, based on developments on this work during the first few decades, see [7], [15], [2], [29], and a wide range of different applications has been reported, see for example, [11], [16]. For some compact descriptions and for references see [26], [27].

Applicability of fully directed graph models to very large systems of units has been emphasized recently, see for example, [6] and is simplified by free-source computational tools within the framework of the R-project, see [19], [18], [1].

Special extensions to **time series** have been developed ([5], [8], [9]), and it has been shown that the independence structure defined with any **structural equation model (SEM)** can be read off a corresponding graph [13]. The result does not extend to the interpretation of SEM parameters. Extensions to point processes and to multilevel models (see **Linear Multilevel Models**) are in progress. Graphical criteria for deciding on the identifiability of special linear models, including hidden variables, have been derived [23], [21], [25], [12], [24].

A new approach to studying properties of graphical Markov models is based on binary matrix forms of graphs [28]. This uses analogies between partial inversion of parameter matrices for linear systems and partial closing of directed and of undirected paths in graphs. The starting point for this are step-wise generating processes, either for systems of linear equations, or for joint distributions.

In both cases the graph consists of a set of nodes, with node i representing random variable Y_i , and a set of directed edges. Each edge is drawn as an arrow outgoing from what is called a *parent node* and pointing to an offspring node. The graph is acyclic, if it is impossible to return to any starting node by following arrows pointing in the same direction. The set of parent nodes of node i is denoted by par_i and the graph is called a *parent graph* if there is a complete ordering of the variables as $(Y_1, \dots, Y_d)$. Either a joint density is given by a recursive sequence of univariate conditional densities, or a covariance matrix is generated by a system of recursive equations.

The joint density f_N , generated over a parent graph with nodes $N = (1, \dots, d)$, and written in a compact notation for conditional densities in terms

2 Graphical Chain Models

of nodes, is

$$f_N = \prod_i f_{i|i+1,\dots,d} = \prod_i f_{i|\text{par}_i}. \quad (1)$$

The conditional independence statement $i \perp j | \text{par}_i$ is equivalent to the factorization $f_{i|\text{par}_i,j} = f_{i|\text{par}_i}$, and it is represented by a missing ij -arrow in the parent graph for $i < j$.

The joint covariance matrix Σ of mean-centered and continuous variables Y_i , generated over a parent graph with nodes $N = (1, \dots, d)$, is given by a system of linear recursive equations with uncorrelated residuals, written as

$$AY = \varepsilon, \quad (2)$$

where A is an upper-triangular matrix with unit diagonal elements, and ε is a residual vector of zero-mean uncorrelated random variables ε . A diagonal form of the residual covariance matrix $\text{cov}(\varepsilon) = \Delta$ is equivalent to specifying that each row of A in (2) defines a linear least squares regression equation ([4], p. 302) for response Y_i regressed on $Y_{i+1}, \dots, Y_d$. For the regression coefficient of Y_j in this regression, it holds for $i < j$:

$$-a_{ij} = \beta_{i|j \cdot \{i+1, \dots, d\} \setminus j} = \beta_{i|j \cdot \text{par}_i \setminus j}. \quad (3)$$

Thus, the vanishing contribution of Y_j to the linear regression of Y_i on $Y_{i+1}, \dots, Y_d$ is represented by zero value in position (i, j) in the upper triangular-part of A .

The types of question that can be answered for these generating processes are: which independencies (either linear or probabilistic not both) are preserved if the order of the variables is modified, or if some of the variables are considered as joint instead of univariate responses, or if some of variables are explicitly omitted, or if a subpopulation is selected? [28]. Joint response models that preserve exactly the independencies of the generating process after omitting some variables and conditioning on others form a slightly extended subclass of SEM models [22], [14].

Sequences of joint responses occur in different types of chain graphs. All these chain graphs have in common that the nodes are arranged in a sequence of say d_{CC} chain components g , each containing one or more nodes. For partially ordered nodes, $N = (1, \dots, g, \dots, d_{CC})$, a joint density is considered in the form

$$f_N = \prod_g f_{g|g+1, \dots, d_{CC}}. \quad (4)$$

Within this broad formulation of chain graphs, one speaks of multivariate-regression chains, whenever, for a given chain component g , variables at nodes i and j are considered conditionally, given all variables in chain components $g+1, \dots, d_{CC}$. Then the univariate and bivariate densities

$$f_{i|g+1, \dots, d_{CC}}, \quad f_{ij|g+1, \dots, d_{CC}} \quad (5)$$

determine the presence or absence of a directed ij -edge, which points to node i in chain component g from a node j in $g+1, \dots, d_{CC}$, or of an undirected ij -edge within g when j itself is in g .

The more traditional form of chain graphs results if, for a given chain component g , variables at nodes i and j are considered conditionally given all other variables in g and the variables in $g+1, \dots, d_{CC}$. Then the univariate and bivariate densities

$$f_{i|g \setminus \{i\}, g+1, \dots, d_{CC}}, \quad f_{ij|g \setminus \{i, j\}, g+1, \dots, d_{CC}} \quad (6)$$

are relevant for a directed ij -edge, which points to node i in chain component g from a node j in $g+1, \dots, d_{CC}$, as well as for an undirected ij -edge within g .

These traditional chain graphs are called *blocked-concentration* Graphs, or, sometimes, LWF (Lauritzen, Wermuth, Frydenberg) graphs. Chain graphs with the undirected components as in blocked-concentration graphs and the directed components as in multivariate regressions graphs are called *concentration-regression graphs*, or, sometimes, AMP (Andersen, Madigan, Perlman) graphs. The statistical models corresponding to the latter for purely discrete variables are the so-called marginal models. These belong to the exponential family of models and have canonical parameters for the undirected components and moment parameters for the directed components.

Stepwise generating processes in univariate responses arise both in observational and in intervention studies. With an intervention, the probability distribution is changed so that the intervening variable is decoupled from all variables in the past that relate directly to it in an observational setting, see [17]. Two main assumptions distinguish ‘causal models with potential outcomes’ (or counterfactual models) from general generating processes in univariate responses. These are (1) unit-treatment additivity, and (2) a notional intervention. These two assumptions, taken together, assure that there are no unobserved

confounders, and that there is no interactive effect on the response by an unobserved variable and the intervening variable. One consequence of these assumptions is for linear models that the effect of the intervening variable on the response averaged over past variables coincides with its conditional effects given past unobserved variables. Some authors have named this a causal effect. For a comparison of different definitions of causality from a statistical viewpoint, including many references, and for the use of graphical Markov models in this context, see [3].

Graphical Methods pre-20th Century

Statistical graphs are such a prominent feature of science today that it is hard to imagine science without them [17, 20, 37]. Surveys indicate that graphs are nearly ubiquitous in journal articles of the natural sciences (although they remain far less common in the behavioral sciences) [12, 31]. Yet graphs have not always been a fixture of science: they were not used during the Scientific Revolution [14], and even a century ago, fewer than a third of published scientific papers included graphs [12]. The slow and uneven rise of statistical graphics has engaged the interest of historians, who have revealed a story of piecemeal growth in graphical methods against a backdrop of controversy and opposition to their use. As Biderman put it, graphical methods have developed in ‘waves of popularity and of neglect’ [2, p. 3].

Early Graphs

At first blush, the near-total absence of graphs during the Scientific Revolution is puzzling. Descartes’s analytical geometry had introduced the requisite framework of Cartesian coordinates in 1637, and other forms of scientific visualization were well developed by the seventeenth century. Galileo, for example, made conspicuous use of geometrical diagrams in reasoning about the laws of acceleration, and numerical tables, anatomical drawings, and maps of heaven and earth were well established in scientific publishing by the end of that century [12, p. 46]. But despite these favorable developments, the seventeenth century saw only scattered uses of graphs, none of them with lasting influence. Most of these graphs, such as Christopher Wren’s line charts of temperature or Edmund Halley’s of barometric pressure (both from the 1680s), were generated by clock-driven instruments, and were used for converting readings to tables of numbers rather than for graphical analysis [1, 34].

The systematic use of graphs – in the modern sense of figures containing axes, scales, and quantitative data – emerged only in the late eighteenth century in the work of a handful of innovators, chief

among them being Johann Lambert and William Playfair. The German natural philosopher Lambert studied phenomena of heat, producing modern-looking line graphs (*see Index Plots*) that showed, for instance, solar warming at different latitudes as a function of the seasons. He drew smooth curves to average out random errors in data and gave explicit consideration to the graphical treatment of error [14, 34]. Often considered the founder of statistical graphics, Playfair, who worked as a draftsman for a London engineering firm, published line charts and **histograms** of economic data in his *Commercial and Political Atlas* of 1786. Among those graphs was his now-famous time series plot of English exports and imports, with the difference between the curves highlighted to represent the country’s balance of trade. In the *Atlas*, Playfair also introduced the **bar graph**, which was supplemented by the **pie chart** in his 1801 *Statistical Breviary*. In both works, Playfair used graphs for purposes of analysis as well as presentation [2]. Areas below and between curves were shaded in color to draw attention to differences, and dashed lines were used to represent projected or hypothetical values. Playfair also designed graphical icons for representing multivariate data [8, 27]. In one version, he used circle charts to code the land areas of countries, and then constructed vertical tangents representing population on the left and revenues on the right. An array of such icons for a dozen or more nations conveyed at a glance the relations between a country’s relative wealth and its available resources, both human and territorial. Playfair’s clear grasp of the cognitive advantages of graphical displays made him an articulate, if sometimes immodest, promoter of graphical methods [5]. From a graph, he wrote, ‘as much information may be obtained in five minutes as would require whole days to imprint on the memory, in a lasting manner, by a table of figures’ [quoted in 8, p. 165].

Despite the foundations laid by Lambert and Playfair, there was little growth in the use of graphical methods for nearly half a century following their work [34]. The slow reception of Playfair’s innovations has been attributed to various factors: the rationalist bias, dating to Descartes, for using graphs to plot abstract equations rather than empirical data; the relative dearth of empirical data suitable for graphical treatment; the belief that graphs are suited only to the teaching of science or its popularization among nonscientists; a perceived lack of rigor in graphical

2 Graphical Methods pre-20th Century

methods; a preference for the numerical precision of tabled numbers; and a general Platonic distrust of visual images as sources of reliable knowledge. The view that statistical graphics represent a vulgar substitute for rigorous numerical methods may have been abetted by Playfair himself, who touted his graphs as a means of communicating data to politicians and businessmen. It seems likely that the disdain of many scientists for graphical methods also stemmed from the dual roots of science in academic natural philosophy and the less prestigious tradition of mechanical arts, of which Playfair was a part [5, 19]. Only when these two traditions successfully merged in the nineteenth century, combining Baconian hands-on manipulation of data with academic mathematical theory, did graphical methods achieve widespread acceptance in science. In Playfair's time, the more common response to graphs was that of the French statistician Jacques Peuchet, who dismissed graphs as 'mere by-plays of the imagination' that are foreign to the aims of science [quoted in 10, p. 295]. Such resistance to graphical methods – which never waned entirely, even during their rise to popularity during the late nineteenth century – is reflected in the fact that the first published graph of a normal distribution [6] appeared more than a century after **De Moivre** had determined the mathematical properties of the normal curve [10].

The use of graphs spread slowly through the first half of the nineteenth century, but not without significant developments. In 1811, the German polymath Alexander von Humboldt, acknowledging Playfair's precedence, published a variety of graphs in his treatise on the Americas. Displaying copious data on the geography, geology, and climate of the New World, he used line graphs as well as divided bar graphs, the latter his own invention. Humboldt echoed Playfair's judgment of the cognitive efficiency of graphs, praising their ability to 'speak to the senses without fatiguing the mind' [quoted in 3, p. 223] and defending them against the charge of being 'mere trifles foreign to science' [quoted in 10, p. 95]. In 1821, the French mathematician J. B. J. Fourier, known for his method of decomposing waveforms, used data from the 1817 Paris census to produce the first published cumulative frequency distribution, later given the name 'ogive' by **Francis Galton**. The application of graphical analysis to human data was further explored by Fourier's student **Adolphe Quetelet** in a series of publications beginning in the 1820s. These

included line charts of birth rates, mortality curves, and probability distributions fitted to histograms of empirical data [32].

Graphical methods also entered science from a different direction with the application of self-registering instruments to biological phenomena. Notable was Carl Ludwig's 1847 invention of the kymograph, which quickly came into common use as a way to make visible a range of effects that were invisible to the naked eye. Hermann von Helmholtz achieved acclaim in the 1850s by touring Europe with his *Froschcurven*, myographic records of the movements of frog muscles. These records included the graphs by which he had measured the speed of the neural impulse, one of the century's most celebrated scientific achievements and one that, as Helmholtz recognized, depended crucially on graphical methods [4, 15]. By midcentury, graphical methods had also gained the attention of philosophers and methodologists. In his influential *Philosophy of the Inductive Sciences* (1837–60), William Whewell hailed the graphical method – which he called the '*method of curves*' – as a fundamental means of discovering the laws of nature, taking its place alongside the traditional inductive methods of Bacon. Based partly on his own investigations of the tides, Whewell judged the method of curves superior to numerical methods, for 'when curves are drawn, the eye often spontaneously detects the law of recurrence in their sinuosities' [36, p. 405]. For such reasons, he even favored the graphical method over the newly developed method of least squares, which was also treated in his text.

The Golden Age of Graphics

The second half of the nineteenth century saw an unprecedented flourishing of graphical methods, leading to its designation as the Golden Age of graphics. According to Funkhouser [10], this period was marked by enthusiasm for graphs not only among scientists and statisticians but also among engineers (notably the French engineers Cheysson and Minard), government officials, and the public. The standardization imposed by the government bureaucracies of the time produced torrents of data well suited to graphical treatment [26]. Under Quetelet's leadership, a series of International Statistical Congresses from 1853 from 1876 staged massive exhibitions of graphical displays (a partial listing of the charts at the 1876

Congress cited 686 items), as well as attempts to standardize the nomenclature of graphs and the rules for their construction. The Golden Age also saw the first published systems for classifying graphical forms, as well as a proliferation of novel graphical formats. In 1857, **Florence Nightingale** produced ‘coxcomb’ plots for displaying the mortality of British soldiers across the cycle of months, a format that survives as today’s rose plots. In 1878, the Italian statistician Luigi Perozzo devised perspective plots called ‘stereograms’ in which complex relations of variables (such as probability of marriage by age and sex) were shown as three-dimensional surfaces. When the results of the ninth U.S. Census were published in 1874, they included such now-standard formats as population pyramids and bilateral frequency polygons. The 1898 report of the eleventh U.S. Census, published toward the end of the Golden Age, contained over 400 graphs and statistical maps in a wide variety of formats, many of them in color. The widespread acceptance of graphs by the end of this era was also signaled by the attention they drew from leading statisticians. During the 1890s, **Karl Pearson**, then a rising star in the world of statistics, delivered a series of lectures on graphical methods at Gresham College. In them, he treated dozens of graphical formats, challenged the ‘erroneous opinion’ that graphs are but a means of popular presentation, and described the graphical method as ‘a *fundamental method of investigating and analyzing statistical material*’ [23, p. 142, emphasis in original].

The spread of graphs among political and economic statisticians during the Golden Age was paralleled by their growing currency in the natural sciences. Funkhouser reports that graphs became ‘an important adjunct of almost every kind of scientific gathering’ [10, p. 330]. Their use was endorsed by leading scientists such as Ernst Mach and Emil du Bois-Reymond on the Continent and Willard Gibbs in America. For his part, Gibbs saw the use of graphs as central to the breakthroughs he achieved in thermodynamics; in fact, his first paper on the subject concerned the design of optimal graphs for displaying abstract physical quantities [14]. The bible of the burgeoning graphics movement was Etienne-Jules Marey’s 1878 masterwork, *La méthode graphique* [22]. This richly illustrated tome covered both statistical graphs and instrument-generated recordings, and included polemics on the cognitive and epistemological advantages of graphical methods.

It was one of many late nineteenth-century works that hailed graphs as the new *langue universelle* of science – a visual language that, true to the positivist ideals of the era, would enhance communication between scientists while neutralizing national origins, ideological biases, and disciplinary boundaries. In 1879, the young G. Stanley Hall, soon to emerge as a leading figure of American psychology, reported in *The Nation* that the graphic method – a method said to be ‘superior to all other modes of describing many phenomena’ – was ‘fast becoming the international language of science’ [13, p. 238]. Having recently toured Europe’s leading laboratories (including Ludwig’s in Leipzig), Hall also reported on the pedagogical applications of graphs he had witnessed at European universities. In an account foreshadowing today’s instructional uses of computerized graphics, he wrote that the graphical method had ‘converted the lecture room into a sort of theatre, where graphic charts are the scenery, changed daily with the theme’ [13, p. 238]. Hall himself would later make extensive use of graphs, including some sophisticated charts with multiple ordinates, in his classic two-volume work *Adolescence* (1904).

Graphs in Behavioral Science

Hall was not alone among the early behavioral scientists in making effective use of graphic methods during the Golden Age. Hermann Ebbinghaus’s 1885 classic *Memory* [7] contained charts showing the repetitions required for memorizing syllable lists as a function of list length, as well as time series graphs that revealed unanticipated periodicities in memory performance, cycles that Ebbinghaus attributed to oscillations in attention. In America, James McKeen Cattell applied graphical methods to one of the day’s pressing issues – the span of consciousness – by estimating the number of items held in awareness from the asymptotes of speed-reading curves. Cattell also analyzed psychophysical data by fitting them against theoretical curves of Weber’s law and his own square-root law, and later assessed the fit of educational data to normal distributions in the course of arguing for differential tuition fees favoring the academically proficient [24]. Cattell’s Columbia colleague Edward L. Thorndike drew heavily on graphical methods in analyzing and presenting the results of the famous puzzle-box experiments that formed

a cornerstone of later behaviorist research. His 1898 paper ‘Animal Intelligence’ [33] contained more than 70 graphs showing various conditioning phenomena and demonstrating that trial-and-error learning occurs gradually, not suddenly as implied by the theory of animal reason.

Despite such achievements, however, the master of statistical graphics among early behavioral scientists was Francis Galton. Galton gained experience with scientific visualization in the 1860s when he constructed statistical maps to chart weather patterns, work which led directly to his discovery of anticyclones. In the 1870s, he introduced the quincunx – a device that demonstrates normal distributions by funneling lead shot across an array of pins – for purposes of illustrating his lectures on heredity and to facilitate his own reasoning about sources of variation and their partitioning [32]. In the 1880s, he began to make contour plots of bivariate distributions by connecting cells of equal frequencies in tabular displays. From these plots, it was a small step to the **scatter plots** that he used to demonstrate regression and, in 1888, to determine the first numerical correlation coefficient, an achievement attained using wholly graphical means [11]. Galton’s graphical intuition, which often compensated for the algebraic errors to which he was prone, was crucial to his role in the founding of modern statistics [25]. Indeed, the ability of graphical methods to protect against numerical errors was recognized by Galton as one of its advantages. ‘It is always well,’ he wrote, ‘to retain a clear geometric view of the facts when we are dealing with statistical problems, which abound with dangerous pitfalls, easily overlooked by the unwary, while they are cantering gaily along upon their arithmetic’ [quoted in 32, p. 291].

Conclusion

By the end of the nineteenth century, statistical graphics had come a long way. Nearly all of the graphical formats in common use today had been established, the Golden Age of graphs had drawn attention to their fertility, and prominent behavioral scientists had used graphs in creative and sophisticated ways. Yet for all of these developments, the adoption of graphical methods in the behavioral sciences would proceed slowly in the following century. At the time of his lectures on graphical techniques in the 1890s, Pearson

had planned to devote an entire book to the subject. But his introduction of the chi-square test in 1900 drew his interests back to numerical methods, and this shift of interests would become emblematic of ensuing developments in the behavioral sciences. It was the inferential statistics of Pearson and his successors (notably **Gossett** and **Fisher**) that pre-occupied psychologists in the century to come [21, 28]. And while the use of hypothesis-testing statistics became nearly universal in the behavioral research of the twentieth century [16], the use of graphical methods lay fallow [9, 29]. Even with the advent of exploratory data analysis (an approach more often praised than practiced by researchers), graphical methods would continue to endure waves of popularity and of neglect, both among statisticians [8, 18, 35] and among behavioral scientists [30, 31].

Graphical Presentation of Longitudinal Data

Introduction

Let us begin with a few kind words about the bubonic plague. In 1538, Thomas Cromwell, the Earl of Essex (1485–1540), issued an injunction (one of 17) in the name of Henry VIII that required the registration of all christenings and burials in every English Parish. The London Company of Parish Clerks compiled weekly *Bills of Mortality* from such registers. This record of burials provided a way to monitor the incidence of plague within the city. Initially, these *Bills* were circulated only to government officials; principal among them, the Lord Mayor and members of the King's Council.

They were first made available to the public in 1594, but were discontinued a year later with the abatement of the plague. However, in 1603, when

the plague again struck London, their publication resumed on a regular basis.

The first serious analysis of the *London Bills* was done by John Graunt in 1662, and in 1710, **Dr. John Arbuthnot**, a physician to Queen Anne, published an article that used the christening data to support an argument (possibly tongue in cheek) for the existence of God. These data also provide supporting evidence for the lack of existence of statistical graphs at that time.

Figure 1 is a simple plot of the annual number of christenings in London from 1630 until 1710. As we will see in a moment, it is quite informative. The preparation of such a plot is straightforward, certainly requiring no more complex apparatus than was available to Dr. Arbuthnot in 1710. Yet, it is highly unlikely that Arbuthnot, or any of his contemporaries, ever made such a plot.

The overall pattern we see in Figure 1 is a trend over 80 years of an increasing number of christenings, almost doubling from 1630 to 1710. A number of fits and starts manifest themselves in

Figure 1 A plot of the annual christenings in London between 1630 and 1710 from the London Bills of Mortality. These data were taken from a table published by John Arbuthnot in 1710

2 Graphical Presentation of Longitudinal Data

substantial jiggles. Yet, each jiggle, save one, can be explained. Some of these explanations are written on the plot. The big dip that began in 1642 can only partially be explained by the onset of the English Civil War. Surely the chaos common to civil war can explain the initial drop, but the war ended in 1649 with the beheading of Charles I at Whitehall, whereas the christenings did not return to their earlier levels until 1660 (1660 marks the end of the protectorate of Oliver and Richard Cromwell and the beginning of the restoration). Graunt offered a more complex explanation that involved the distinction between births and christenings, and the likelihood that Anglican ministers would not enter children born to Catholics or Protestant dissenters into the register.

Many of the other irregularities observed are explained in Figure 1, but what about the mysterious drop in 1704? That year has about 4000 fewer christenings than one might expect from observing the adjacent data points. What happened? There was no sudden outbreak of a war or pestilence, no

great civil uprising, nothing that could explain this enormous drop.

The plot not only reveals the anomaly, it also presents a credible explanation. In Figure 2, we have duplicated the christening data and drawn a horizontal line across the plot through the 1704 data point. In doing so, we immediately see that the line goes through exactly one other point – 1674. If we went back to Arbuthnot's table, we would see that in 1674 the number of christenings of boys and girls were 6113 and 5738, exactly the same number as he had for 1704. Thus, the 1704 anomaly is likely to be a copying error! In fact, the correct figure for that year is 15 895 (8153 boys and 7742 girls), which lies comfortably between the christenings of 1703 and 1705 as expected.

It seems reasonable to assume that if Arbuthnot had noticed such an unusual data point, he would have investigated, and finding a clerical error, would have corrected it. Yet he did not. He did not, despite the fact that when graphed the error stands out, literally, like a sore thumb. Thus, we must conclude

Figure 2 The solution to the mystery of 1704 is suggested by noting that only one other point (1674) had exactly the same values as the 1704 outlier. This coincidence provided the hint that allowed Zabell [11] to trace down Arbuthnot's clerical error. (Data source: Arbuthnot 1710)

that he never graphed his data. Why not? The answer, very simply, is that graphs were not yet part of the statistician's toolbox. (There were a very small number of graphical applications prior to 1710, but they were not widely circulated and Arbuthnot, a very clever and knowledgeable scientist, had likely not been familiar with them.)

The Beginnings of Graphs

Graphs are the most important tool for examining longitudinal data because they convey comparative information in ways that no table or description ever could. Trends, differences, and associations are effortlessly seen in the blink of an eye. The eye perceives immediately what the brain would take much longer to deduce from a table of numbers. This is what makes graphs so appealing – they give numbers a voice, allowing them to speak clearly. Graphs and charts not only show what numbers tell, they also help scientists tease out the critical clues from their data, much as a detective gathers clues at the scene of a crime. Graphs are truly international – a German can read the same graph that an Australian draws. There is no other form of communication that more appropriately deserves the description 'universal language.'

Who invented this versatile device? Have graphs been around for thousands of years, the work of inventors unknown? The truth is that statistical graphs were not invented in the remote past; they were not at all obvious and their creator lived only two centuries ago. He was a man of such unusual skills and experience that had he not devised and published his charts during the Age of Enlightenment we might have waited for another hundred years before the appearance of statistical graphs.

The Scottish engineer and political economist, William Playfair (1759–1823) is the principal inventor of statistical graphs. Although one may point to solitary instances of simple line graphs that precede Playfair's work (see Wainer & Velleman, [10]), such examples generally lack refinement and, without exception, failed to inspire others. In contrast, Playfair's graphs were detailed and well drawn; they appeared regularly over a period of more than 30 years; and they introduced a surprising variety of practices that are still in use today. He invented three of the four basic forms: the statistical line

graph, the **bar chart**, and the **pie chart**. The other important basic form – the **scatterplot** – did not appear until at least a half century later (some credit Herschel [4] with its first use, others believe that Herschel's plot was a time-series plot, no different than Playfair's). Playfair also invented other graphical elements, for example, the circle diagram and statistical Venn diagram; but these innovations are less widely used.

Two Time-series Line Graphs

In 1786, Playfair [5] published his *Commercial and Political Atlas*, which contained 44 charts, but no maps; all of the charts, save one, were variants of the statistical time-series line graph. Playfair acknowledged the influence of the work of Joseph Priestley (1733–1804), who had also conceived of representing time geometrically [6, 7]. The use of a grid with time on the horizontal axis was a revolutionary idea, and the representation of the lengths of reigns of monarchs by bars of different lengths allowed immediate visual comparisons that would otherwise have required significant mental arithmetic. An interesting sidelight to Priestley's plot is that he accompanied the original (1765) version with extensive explanations, which were entirely omitted in the 1769 elaboration when he realized how naturally his audience could comprehend it (Figure 3).

At about the same time that Priestley was drafting his time lines, the French physician Jacques Barbeau-Dubourg (1709–1779) and the Scottish philosopher Adam Ferguson (1723–1816) produced plots that followed a similar principle. In 1753, Dubourg published a scroll that was a complex timeline spanning the 6480 years from The Creation until Dubourg's time. This is demarked as a long thin line at the top of the scroll with the years marked off vertically in small, equal, one-year increments. Below the timeline, Dubourg laid out his record of world history. He includes the names of kings, queens, assassins, sages, and many others, as well as short phrases summarizing events of consequence. These are fixed in their proper place in time horizontally and grouped vertically either by their country of origin or in Dubourg's catch-all category at the bottom of the chart 'événements mémorables.' In 1780, Ferguson published a timeline of the birth and death of civilizations that begins at the time of the Great Flood

Figure 3 Lifespans of 59 famous people in the six centuries before Christ (Priestley, [6]). Its principal innovation is the use of the horizontal axis to depict time. It also uses dots to show the lack of precise information on the birth and/or death of the individual shown

(2344 BC – indicating clearly, though, that this was 1656 years after The Creation) and continued until 1780. And in 1782, the Scottish minister James Playfair (unrelated to William), published *A System of Chronology*, in the style of Priestley.

The motivation behind the drafting of graphical representations of longitudinal data remains the same today as it was in eighteenth-century France. Dubourg declared that history has two ancillary fields: geography and chronology. Of the two he believed that geography was the more developed as a means for studying history, calling it ‘lively, convenient, attractive.’ By comparison, he characterizes chronology as ‘dry, laborious, unprofitable, offering the spirit a welter of repulsive dates, a prodigious multitude of numbers which burden the memory.’ He believed that by wedding the methods of geography to the data of chronology he could make the latter as accessible as the former. Dubourg’s name for his invention *chronographie* tells a great deal about what he intended, derived as it is from the Greek *chronos*

(time) and *grapheikos* (writing). Dubourg intended to provide the means for chronology to be a science that, like geography, speaks to the eyes and the imagination, ‘a picture moving and animated.’

Joseph Priestley used his line chart to depict the life spans of famous figures from antiquity; Pythagoras, Socrates, Pericles, Livy, Ovid, and Augustus, all found their way onto Priestley’s plot. Priestley’s use of this new tool was clearly in the classical tradition.

Twenty-one years later, William Playfair used a variant on the same form (See Figure 4) to show the extent of imports and exports of Scotland to 17 other places. Playfair, as has been amply documented (Spence & Wainer, [8]), was an iconoclast and a versatile borrower of ideas who could readily adapt the chronological diagram to show economic data; in doing so, he invented the bar chart. Such unconventional usage did not occur to his more conservative peers in Great Britain, or on the Continent. He had previously done something equally

Exports and imports of Scotland to and from different parts for one year from Christmas 1780 to Christmas 1781

The Upright Divisions are ten thousand pounds each. The black lines are Exports, the ribbed lines, imports.

Published as the Act directs June 7th 1786 by W^m. Playfair

6 Graphical Presentation of Longitudinal Data

novel when he adapted the line graph, which was becoming popular in the natural sciences, to display economic time series. However, Playfair did not choose to adapt Priestley's chronological diagram because of any special affection for it, but rather of necessity, since he lacked the time-series data he needed to show what he wanted. He would have preferred a line chart similar to the others in his *Atlas*. In his own words,

'The limits of this work do not admit of representing the trade of Scotland for a series of years, which, in order to understand the affairs of that country, would be necessary to do. Yet, though they cannot be represented at full length, it would be highly blameable entirely to omit the concerns of so considerable a portion of this kingdom.'

Playfair's practical subject matter provides a sharp contrast to the classical content chosen by Priestley to illustrate his invention.

In 1787, shortly after publishing the *Atlas*, Playfair moved to Paris. Thomas Jefferson spent five years as ambassador to France (from 1784 until 1789). During that time, he was introduced to Playfair personally [2], and he was certainly familiar with his graphical inventions. One of the most important influences on Jefferson at William and Mary College in Virginia was his tutor, Dr. William Small, a Scots teacher of mathematics and natural philosophy – Small was Jefferson's only teacher

during most of his time as a student. From Small, Jefferson received both friendship and an abiding love of science. Coincidentally, through his friendships with James Watt and John Playfair, Small was responsible for introducing the 17-year-old William Playfair to James Watt, with the former serving for three years as Watt's assistant and draftsman in Watt's steam engine business in Birmingham, England.

Although Jefferson was a philosopher whose vision of democracy helped shape the political structure of the emerging American nation, he was also a farmer, a scientist, and a revolutionary whose feet were firmly planted in the American ethos. So it is not surprising that Jefferson would find uses for graphical displays that were considerably more down to earth than the life spans of heroes from classical antiquity. What is surprising is that he found time, while President of the United States, to keep a keen eye on the availability of 37 varieties of vegetables in the Washington market and compile a chart of his findings (a detail of which is shown in Figure 5).

When Playfair had longitudinal data, he made good use of them, producing some of the most beautiful and informative graphs of such data ever made. Figure 6 is one remarkable example of these. Not only is it the first 'skyrocketing government debt' chart but it also uses the innovation of an irregularly

Figure 5 An excerpt from a plot by Thomas Jefferson showing the availability of 16 vegetables in the Washington market during 1802. This figure is reproduced, with permission, from Froncek ([3], p. 101)

spaced grid along the time axis to demark events of important economic consequence.

Modern Developments

Recent developments in displaying longitudinal data show remarkably few modifications to what was developed more than 200 years ago, fundamentally because Playfair got it right. Modern high-speed computing allows us to make more graphs faster, but they are not, in any important way, different from those Playfair produced. One particularly useful modern example (Figure 7) is taken from Diggle, Heagerty, Liang & Zeger ([1], p. 37–38), which is a hybrid plot combining a scatterplot with a line drawing. The data plotted are the number of CD4+ cells found in HIV positive individuals over time. (CD4+ cells orchestrate the body's immunoresponse to infectious agents. HIV attacks this cell and so keeping track of the number of CD4+ cells allows us to monitor the progress of the disease.) Figure 7 contains the

longitudinal data (*see Longitudinal Data Analysis*) from 100 HIV positive individuals over a period that begins about two years before HIV was detectable (seroconversion) and continues for four more years. If the data were to be displayed as a **scatterplot**, the time trend would not be visible because we have no idea of which points go with which. But (Figure 7(a)) if we connect all the dots together appropriately, the graph is so busy that no pattern is discernable. Diggle et al. [1] propose a compromise solution in which the data from a small, randomly chosen, subset of subjects are connected (Figure 7(b)). This provides a guide to the eye of the general shape of the longitudinal trends. Other similar schemes are obviously possible: for example, fitting a function to the aggregate data and connecting the points for some of the residuals to look for idiosyncratic trends.

A major challenge of data display is how to represent multidimensional data on a two-dimensional surface (*see Multidimensional Scaling; Principal Component Analysis*). When longitudinal data are

Figure 7 Figures 3.4 and 3.5 from Diggle et al., [1] – reprinted with permission (p. 37–38), showing CD4+ counts against time since seroconversion, with sequences of data on each subject connected (a) or connecting only a randomly selected subset of subjects (b)

Figure 8 An 1869 plot by Charles Joseph Minard, *Tableaux Graphiques et Cartes Figuratives de M. Minard, 1845–1869* depicting the size of Hannibal's Army as it crossed from Spain to Italy in his ill-fated campaign in the Second Punic War (218–202 bc). A portfolio of Minard's work is held by the Bibliothèque de l'École Nationale des Ponts et Chaussées, Paris. This figure was reproduced from Edward R. Tufte, *The Visual Display of Quantitative Information* (Cheshire, Connecticut © 1983, 2001), p. 176. with permission

themselves multivariate (see **Multivariate Analysis: Overview**), this is a problem that has few completely satisfying solutions. Interestingly, we must look back more than a century for the best of these. In 1846, the French civil engineer Charles Joseph Minard (1781–1870) developed a format to show longitudinal data on a geographic background. He used a metaphorical data river flowing across the landscape tied to a timescale. The river's width was proportional to the amount of materials being depicted (e.g., freight, immigrants), flowing from one geographic region to another. He used this almost exclusively to portray the transport of goods by water or land. This metaphor was employed to perfection in his 1869 graphic (Figure 8), in which, through the substitution of soldiers for merchandise, he was able to show the catastrophic loss of life in Napoleon's ill-fated Russian campaign. The rushing river of 422 000 men that crossed into Russia when compared with the returning trickle of 10 000 'seemed to defy the pen of the historian by its brutal eloquence.' This now-famous display has been called (Tufte, [9]) 'the best graph ever produced.' Minard paired his Napoleon plot with a parallel one depicting the loss of life in the Carthaginian general Hannibal's ill-fated crossing of the Alps in the Second Punic War. He began his campaign in 218 BC

in Spain with more than 97 000 men. His bold plan was to traverse the Alps with elephants and surprise the Romans with an attack from the north, but the rigors of the voyage reduced his army to only 6000 men. Minard's beautiful depiction shows the Carthaginian river that flowed across Gaul being reduced to a trickle by the time they crossed the Alps. This chart has been less often reproduced than Napoleon's march and so we prefer to include it here.

Note

1. This exposition is heavily indebted to the scholarly work of Sandy Zabell, to whose writings the interested reader is referred for a much fuller description (Zabell, [11, 12]). It was Zabell who first uncovered Arbuthnot's clerical error.

Growth Curve Modeling

‘Time is the one immaterial object which we cannot influence – neither speed up nor slow down, add to nor diminish.’ Maya Angelou

A growth curve model – also known as an *individual growth model* or a *multilevel model for change* – describes how a continuous outcome changes systematically over time. Generations of behavioral scientists have been interested in modeling change, but for decades, the prevailing view was that it was impossible to model change well [2]. During the 1980s, however, methodologists working within a variety of different disciplines developed a class of appropriate methods – known variously as random coefficient models, multilevel models, mixed models, linear mixed effects models and hierarchical linear models – that permit the modeling of change (see **Linear Multilevel Models**). Today we know that it is possible to model change, and do it well, as long as you have longitudinal data [7, 11] (see **Longitudinal Data Analysis**).

Growth curve models can be fit to many different types of longitudinal data sets. The research design can be experimental or observational, prospective or retrospective. Time can be measured in whatever units make sense – from seconds to years, sessions to semesters. The data collection schedule can be fixed (everyone has the same periodicity) or flexible (each person has a unique schedule); the number of waves of data per person can be identical or varying. And do not let the term ‘growth model’ fool you – these models are appropriate for outcomes that *decrease* over time (e.g., weight loss among dieters) or exhibit complex trajectories (including plateaus and reversals).

Perhaps the most intuitively appealing way of postulating a growth curve model is to link it to two distinct questions about change, each arising from a specific level in a natural hierarchy:

- At level-1 – the within-person level – we ask about each person’s individual change trajectory. How does the outcome change over time? Does it increase, decrease, or remain steady? Is change linear or nonlinear?
- At level-2 – the between-person (or interindividual) level – we ask about predictors that might

explain differences among individual’s change trajectories. On average, do men’s and women’s trajectories begin at the same level? Do they have the same rates of change?

These two types of questions – the former within-person and the latter between-persons – lead naturally to the specification of two sets of statistical models that together form the overall multilevel model for change (see **Linear Multilevel Models**).

We illustrate ideas using three waves of data collected by researchers tracking the cognitive performance of 103 African-American infants born into low-income families in the United States [1]. When the children were 6 months old, approximately half ($n = 58$) were randomly assigned to participate in an intensive early intervention program designed to enhance their cognitive performance; the other half ($n = 45$) received no intervention and constituted a control group. Here, we examine the effects of program participation on changes in cognitive performance as measured by a nationally normed test administered three times, at ages 12, 18 and 24 months.

In the left-hand panel of Figure 1, we plot the cognitive performance (COG) of one child in the control group versus his age (rescaled here in years). Notice the downward trend, which we summarize – rather effectively – using an ordinary least squares (OLS) linear regression line (see **Multiple Linear Regression**). Especially when you have few waves of data, it is difficult to argue for anything except a linear within-person model. When examining Figure 1, also note that the hope that we would be assessing whether program participants experience a faster rate of *growth* is confronted with the reality that we may instead be assessing whether they experience a slower rate of *decline*.

The Level-1 Model

The level-1 model represents the change we expect each member of the population to experience during the time period under study (here, the second year of life). Assuming that change is a linear function of age, a reasonable level-1 model is:

$$Y_{ij} = [\pi_{0i} + \pi_{1i}(AGE_{ij} - 1)] + \varepsilon_{ij} \quad (1)$$

This model asserts that, in the population from which this sample was drawn, Y_{ij} , the value of COG

2 Growth Curve Modeling

Figure 1 Developing a growth curve model using data on cognitive performance over time. The left-hand panel plots the cognitive performance (COG) of one child in the control group versus his age (rescaled here in years). The middle panel presents fitted OLS trajectories for a random subset of 28 children (coded using solid lines for program participants and dashed lines for nonparticipants). The right-hand panel presents fitted change trajectories for program participants and nonparticipants

for child i at time j , is a linear function of his (or her) age on that occasion (AGE_{ij}). The model assumes that a straight line adequately represents each person's true change trajectory and that any deviations from linearity in sample data result from random error (ε_{ij}). Although everyone in this dataset was assessed on the same three occasions (ages 1.0, 1.5, and 2.0), this basic level-1 model can be used in a wide variety of datasets, even those in which the timing and spacing of waves varies across people.

The brackets in (1) identify the model's structural component, which represents our hypotheses about each person's true trajectory of change over time. The model stipulates that this trajectory is linear in age and has individual growth parameters, π_{0i} and π_{1i} , which characterize its shape for the i th child in the population. If the model is appropriate, these parameters represent fundamental features of each child's true growth trajectory, and as such, become the objects of prediction when specifying the linked level-2 model.

An important feature of the level-1 specification is that the researcher controls the substantive meaning of these parameters by choosing an appropriate metric for the temporal predictor. For example, in this level-1 model, the intercept, π_{0i} , represents child i 's true cognitive performance at age 1. This interpretation accrues because we *centered* AGE in the level-1 model using the predictor $(AGE - 1)$. Had we not centered

age, π_{0i} would represent child i 's true value of Y at age 0, which is meaningless and predates the onset of data collection. Centering time on the first wave of data collection is a popular approach because it allows us to interpret π_{0i} using simple nomenclature: it is child i 's true initial status, his or her true status at the beginning of the study.

The more important individual growth parameter is the slope, π_{1i} , which represents the rate at which individual i changes over time. By clocking age in years (instead of the original metric of months), we can adopt the simple interpretation that π_{1i} represents child i 's true annual rate of change. During the single year under study – as child i goes from age 1 to 2 – his trajectory rises by π_{1i} . Because we hypothesize that each individual in the population has his (or her) own rate of change, this growth parameter has the subscript i .

In specifying a level-1 model, we implicitly assume that all the true individual change trajectories in the population have a common algebraic form. But because each person has his or her own individual growth parameters, we do not assume that everyone follows the same trajectory. The level-1 model allows us to distinguish the trajectories of different people using just their individual growth parameters. This leap is the cornerstone of growth curve modeling because it means that we can study interindividual

differences in growth *curves* by studying interindividual variation in growth *parameters*. This allows us to recast vague questions about the relationship between ‘change’ and predictors as specific questions about the relationship between the individual growth parameters and predictors.

The Level-2 Model

The level-2 model codifies the relationship between interindividual differences in the change trajectories (embodied by the individual growth parameters) and time-invariant characteristics of individuals. To develop an intuition for this model, examine the middle panel of Figure 1, which presents fitted OLS trajectories for a random subset of 28 children in the study (coded using solid lines for program participants and dashed lines for nonparticipants). As noted for the one child in the left panel, cognitive performance (on this age-standardized scale) tends to decline over time. In addition, program participants have generally higher scores at age 1 and decline less precipitously over time. This suggests that their intercepts are higher but their slopes are shallower. Also note the substantial interindividual heterogeneity *within* groups. Not all participants have higher intercepts than nonparticipants; not all nonparticipants have steeper slopes. Our level-2 model must simultaneously account for both the general patterns (the between-group differences in intercepts and slopes) *and* interindividual heterogeneity in patterns within groups.

This suggests that an appropriate level-2 model will have four specific features. First, the level-2 outcomes will be the level-1 individual growth parameters (here, π_{0i} and π_{1i} from (1)). Second, the level-2 model must be written in separate parts, one distinct model for each level-1 growth parameter; (here, π_{0i} and π_{1i}). Third, each part must specify a relationship between the individual growth parameter and the predictor (here, PROGRAM, which takes on only two values, 0 and 1). Fourth, each model must allow individuals who share common predictor values to vary in their individual change trajectories. This means that each level-2 model must allow for stochastic variation (also known as random variation) in the individual growth parameters.

These considerations lead us to postulate the following level-2 model:

$$\begin{aligned}\pi_{0i} &= \gamma_{00} + \gamma_{01} \text{PROGRAM} + \zeta_{0i} \\ \pi_{1i} &= \gamma_{10} + \gamma_{11} \text{PROGRAM} + \zeta_{1i}\end{aligned}\quad (2)$$

Like all level-2 models, (2) has more than one component; taken together, they treat the intercept (π_{0i}) and the slope (π_{1i}) of an individual’s growth trajectory as level-2 outcomes that may be associated with identified predictors (here, PROGRAM). As in regular regression, we can modify the level-2 model to include other predictors, adding, for example, maternal education or family size. Each component of the level-2 model also has its own residual – here, ζ_{0i} and ζ_{1i} – that permits the level-1 parameters (the π ’s) to differ across individuals.

The structural parts of the level-2 model contain four level-2 parameters – γ_{00} , γ_{01} , γ_{10} , and γ_{11} – known collectively as the *fixed effects*. The fixed effects capture systematic interindividual differences in change trajectories according to values of the level-2 predictor(s). In (2), γ_{00} and γ_{10} are known as level-2 intercepts; γ_{01} and γ_{11} are known as level-2 slopes. As in regular regression, the slopes are of greater interest because they represent the effect of predictors (here, the effect of PROGRAM) on the individual growth parameters. You interpret the level-2 parameters much like regular regression coefficients, except that they describe variation in ‘outcomes’ that are level-1 individual growth parameters. For example, γ_{00} represents the average true initial status (cognitive score at age 1) for nonparticipants, while γ_{01} represents the hypothesized *difference* in average true initial status between groups. Similarly, γ_{10} represents the average true annual rate of change for nonparticipants, while γ_{11} represents the hypothesized difference in average true annual rate of change between groups. The level-2 slopes, γ_{01} and γ_{11} , capture the effects of PROGRAM. If γ_{01} and γ_{11} are nonzero, the average population trajectories in the two groups differ; if they are both 0, they are the same. The two level-2 slope parameters therefore address the question: What is the difference in the average trajectory of true change associated with program participation?

An important feature of both the level-1 and level-2 models is the presence of stochastic terms – ε_{ij} at level-1, ζ_{0i} and ζ_{1i} at level-2 – also known as residuals. In the level-1 model, ε_{ij} accounts for the difference between an individual’s true and observed trajectory. For these data, each level-1 residual represents that part of child i ’s value of COG at time j not predicted by his (or her) age. The level-2 residuals, ζ_{0i} and ζ_{1i} , allow each person’s individual growth parameters to be scattered around their relevant population averages. They represent those

4 Growth Curve Modeling

portions of the outcomes – the individual growth parameters – that remain ‘unexplained’ by the level-2 predictor(s). As is true of most residuals, we are usually less interested in their specific values than in their variance. The level-1 residual variance, σ_ε^2 , summarizes the scatter of the level-1 residuals around each person’s true change trajectory. The level-2 residual variances, σ_0^2 and σ_1^2 , summarize the variation in true individual intercept and slope around the average trajectories *left over* after accounting for the effect(s) of the model’s predictor(s). As a result, these level-2 residual variances are *conditional* residual variances. Conditional on the model’s predictors, σ_0^2 represents the population residual variance in true initial status and σ_1^2 represents the population residual variance in true annual rate of change. The level-2 variance components allow us to address the question: How much heterogeneity in true change remains after accounting for the effects of program participation?

But there is another complication at level-2: might there be an association between individual initial status and individual rates of change? Children who begin at a higher level may have higher (or lower) rates of change. To account for this possibility, we permit the level-2 residuals to be correlated. Since ζ_{0i} and ζ_{1i} represent the deviations of the individual growth parameters from their population averages, their population covariance, σ_{01} , summarizes the association between true individual intercepts and slopes. Again because of their conditional nature, the population covariance of the level-2 residuals, σ_{01} , summarizes the magnitude and direction of the association between true initial status and true annual rate of change, controlling for program participation. This parameter allows us to address the question: Controlling for program participation, are true initial status and true rate of change related?

To fit the model to data, we must make some distributional assumptions about the residuals. At level-1, the situation is relatively simple. In the absence of evidence suggesting otherwise, we usually invoke the classical normality assumption, $\varepsilon_{ij} \sim N(0, \sigma_\varepsilon^2)$. At level-2, the presence of two (or sometimes more) residuals necessitates that we describe their underlying behavior using a **bivariate (or multivariate) distribution**:

$$\begin{bmatrix} \zeta_{0i} \\ \zeta_{1i} \end{bmatrix} \sim N\left(\begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} \sigma_0^2 & \sigma_{01} \\ \sigma_{10} & \sigma_1^2 \end{bmatrix}\right) \quad (3)$$

The complete set of residual variances and covariances – both the level-2 error variance-covariance matrix and the level-1 residual variance, σ_ε^2 – is known as the model’s **variance components**.

The Composite Growth Curve Model

The level-1/level-2 representation is not the only specification of a growth curve model. A more parsimonious representation results if you collapse the level-1 and level-2 models together into a single *composite* model. The composite representation, while identical to the level-1/level-2 specification mathematically, provides an alternative way of codifying hypotheses and is the specification required by many multilevel statistical software programs.

To derive the composite specification – also known as the *reduced form* growth curve model – notice that any pair of linked level-1 and level-2 models share some common terms. Specifically, the individual growth parameters of the level-1 model are the outcomes of the level-2 model. We can therefore collapse the submodels together by substituting for π_{0i} and π_{1i} from the level-2 model in (2) into the level-1 model (in (1)). Substituting the more generic temporal predictor $TIME_{ij}$ for the specific predictor ($AGE_{ij}-1$), we write:

$$\begin{aligned} Y_{ij} &= \pi_{0i} + \pi_{1i} TIME_{ij} + \varepsilon_{ij} \\ &= (\gamma_{00} + \gamma_{01} PROGRAM_i + \zeta_{0i}) \\ &\quad + (\gamma_{10} + \gamma_{11} PROGRAM_i + \zeta_{1i})TIME_{ij} + \varepsilon_{ij} \end{aligned} \quad (4)$$

Multiplying out and rearranging terms yields the *composite model*:

$$\begin{aligned} Y_{ij} &= [\gamma_{00} + \gamma_{10} TIME_{ij} + \gamma_{01} PROGRAM_i \\ &\quad + \gamma_{11}(PROGRAM_i \times TIME_{ij})] \\ &\quad + [\zeta_{0i} + \zeta_{1i} TIME_{ij} + \varepsilon_{ij}] \end{aligned} \quad (5)$$

where we once again use brackets to distinguish the model’s structural and stochastic components.

Even though the composite specification in (5) appears more complex than the level-1/level-2 specification, the two forms are logically and mathematically equivalent. The level-1/level-2 specification is often more substantively appealing; the composite specification is algebraically more parsimonious. In addition, the γ ’s in the composite model describe patterns of change in a different way. Rather than

postulating first how COG is related to TIME and the individual growth parameters, and second how the individual growth parameters are related to PROGRAM, the composite specification postulates that COG depends *simultaneously* on: (a) the level-1 predictor, TIME; (b) the level-2 predictor, PROGRAM, and (c) the *cross-level* interaction, PROGRAM $\times$ TIME. From this perspective, the composite model's structural portion strongly resembles a regular regression model with predictors, TIME and PROGRAM, appearing as main-effects (associated with γ_{10} and γ_{01} respectively) and in a *cross-level* interaction (associated with γ_{11}).

How did this cross-level interaction arise, when the level-1/level-2 specification appears to have no similar term? Its appearance arises from the 'multiplying-out' procedure used to generate the composite model. When we substitute the level-2 model for π_{1i} into its appropriate position in the level-1 model, the parameter γ_{11} , previously associated only with PROGRAM, gets multiplied by TIME. In the composite model, then, this parameter becomes associated with the interaction term, PROGRAM $\times$ TIME. This association makes sense if you consider the following logic. When γ_{11} is nonzero in the level-1/level-2 specification, the *slopes* of the change trajectories differ according to values of PROGRAM. Stated another way, the effect of TIME (whose effect is represented by the slopes of the change trajectories) differs by levels of PROGRAM. When the effects of one predictor (here, TIME) differ by the levels of another predictor (here, PROGRAM), we say that the two predictors *interact*. The cross-level interaction in the composite specification codifies this effect.

Another distinctive feature of the composite model is its 'composite residual', the three terms in the second set of brackets on the right side of (5) that combine together the one level-1 residual and the two level-2 residuals:

$$\text{Composite residual: } [\zeta_{0i} + \zeta_{1i} \text{ TIME}_{ij} + \varepsilon_{ij}]$$

Although the constituent residuals have the same meaning under both representations, the composite residual provides valuable insight into our assumptions about the behavior of residuals over time. Instead of being a simple sum, the second level-2 residual, ζ_{1i} , is multiplied by the level-1 predictor, TIME. Despite its unusual construction, the interpretation of the composite residual is straightforward: it describes the difference between the

observed and predicted value of Y for individual i on occasion j .

The mathematical form of the composite residual reveals two important properties about the occasion-specific residuals not readily apparent in the level-1/level-2 specification: they can be both *autocorrelated* and *heteroscedastic* within person. These are exactly the kinds of properties that you would expect among residuals for repeated measurements of a changing outcome.

When residuals are heteroscedastic, the unexplained portions of each person's outcome have unequal variances across occasions of measurement. Although heteroscedasticity has many roots, one major cause is the effects of omitted predictors – the consequences of failing to include variables that are, in fact, related to the outcome. Because their effects have nowhere else to go, they bundle together, by default, into the residuals. If their impact differs across occasions, the residual's magnitude may differ as well, creating heteroscedasticity. The composite model allows for heteroscedasticity via the level-2 residual ζ_{1i} . Because ζ_{1i} is multiplied by TIME in the composite residual, its magnitude can differ (linearly, at least, in a linear level-1 sub-model) across occasions. If there are systematic differences in the *magnitudes* of the composite residuals across occasions, there will be accompanying differences in residual *variance*, hence heteroscedasticity.

When residuals are autocorrelated, the unexplained portions of each person's outcome are correlated with each other across repeated occasions. Once again, omitted predictors, whose effects are bundled into the residuals, are a common cause. Because their effects may be present identically in each residual over time, an individual's residuals may become linked across occasions. The presence of the time-invariant ζ_{0i} 's and ζ_{1i} 's in the composite residual of (5) allows the residuals to be autocorrelated. Because they have only an 'i' subscript (and no 'j'), they feature identically in each individual's composite residual on every occasion, allowing for autocorrelation across time.

Fitting Growth Curve Models to Data

Many different software programs can fit growth curve models to data. Some are specialized packages written expressly for this purpose (e.g., HLM,

6 Growth Curve Modeling

Table 1 Results of fitting a growth curve for change to data ($n = 103$). This model predicts cognitive functioning between ages 1 and 2 years as a function of AGE-1 (at level-1) and PROGRAM (at level-2)

		Parameter	Estimate	Age	z
Fixed effects					
Initial status, π_{0i}	Intercept	γ_{00}	107.84***	2.04	52.97
	PROGRAM	γ_{01}	6.85*	2.71	2.53
Rate of change, π_{1i}	Intercept	γ_{10}	-21.13***	1.89	-11.18
	PROGRAM	γ_{11}	5.27*	2.52	2.09
Variance components					
Level-1:	Within-person, ε_{ij}	σ_{ε}^2	74.24***

	In rate of change, ζ_{1i}	σ_1^2	12.29		
	Covariance between ζ_{0i} and ζ_{1i}	σ_{01}	-36.41		

* $p < .05$, ** $p < .01$, *** $p < .001$

Note: Full ML, HLM

MLwiN, and MIXREG). Others are part of popular multipurpose software packages including SAS (PROC MIXED and PROC NLMIXED), SPSS (MIXED), STATA (xtreg and gllamm) and SPLUS (NLME) (see **Software for Statistical Analyses**). At their core, each program does the same job: it fits the growth model to data and provides parameter estimates, measures of precision, diagnostics, and so on. There is also some evidence that all the different packages produce the same, or similar, answers to a given problem [5]. So, in one sense, it does not matter which program you choose. But the packages do differ in many important ways including the ‘look and feel’ of their interfaces, their ways of entering and preprocessing data, their model specification process (the level-1/level-2 specification or the composite specification), their estimation methods (e.g., full **maximum likelihood** vs restricted maximum likelihood – see **Direct Maximum Likelihood Estimation**), their strategies for hypothesis testing, and provision of diagnostics. It is beyond the scope of this entry to discuss these details. Instead, we turn to the results of fitting the growth curve model to data using one statistical program, HLM. Results are presented in Table 1.

Interpreting the Results of Fitting the Growth Curve Model to Data

The fixed effects parameters – the γ ’s of (2) and (5) – quantify the effects of predictors on the individual change trajectories. In our example, they quantify the relationship between the individual growth

parameters and program participation. We interpret these estimates much as we do any regression coefficient, with one key difference: the level-2 ‘outcomes’ that these fixed effects describe are level-1 individual growth parameters. In addition, you can conduct a hypothesis test for each fixed effect using a single parameter test (most commonly, examining the null hypothesis $H_0: \gamma = 0$). As shown in Table 1, we reject all four null hypotheses, suggesting that each parameter plays a role in the story of the program’s effect on children’s cognitive development.

Substituting the $\hat{\gamma}$ ’s in Table 1 into the level-2 model in (2), we have:

$$\begin{aligned}\hat{\pi}_{0i} &= 107.84 + 6.85 \text{ PROGRAM}_i \\ \hat{\pi}_{1i} &= -21.13 + 5.27 \text{ PROGRAM}_i\end{aligned}\quad (6)$$

The first part of the fitted model describes the effects of PROGRAM on initial status; the second part describes its effects on the annual rates of change.

Begin with the first part of the fitted model, for initial status. In the population from which this sample was drawn, we estimate the true initial status (COG at age 1) for the average nonparticipant to be 107.84; for the average participant, we estimate that it is 6.85 points higher (114.69). In rejecting (at the .001 level) the null hypotheses for the two level-2 intercepts, we conclude that the average nonparticipant had a nonzero cognitive score at age 1 (hardly surprising!) but experienced a statistically significant decline over time. Given that this was a randomized trial, you may be surprised to find that the initial status of program participants is 6.85 points

higher than that of nonparticipants. Before concluding that this differential in initial status casts doubt on the randomization mechanism, remember that the intervention started *before* the first wave of data collection, when the children were already 6 months old. This modest 7-point elevation in initial status may reflect early treatment gains attained between ages 6 months and 1 year.

Next examine the second part of the fitted model, for the annual rate of change. In the population from which this sample was drawn, we estimate the true annual rate of change for the average nonparticipant to be -21.13 ; for the average participant, we estimate it to be 5.27 points higher (-15.86). In rejecting (at the .05 level) the null hypotheses for the two level-2 slopes, we conclude that the differences between program participants and nonparticipants in their mean annual rates of change is statistically significant. The average nonparticipant dropped over 20 points during the second year of life; the average participant dropped just over 15. The cognitive performance of both groups of children declines over time, but program participation slows the rate of decline.

Another way of interpreting fixed effects is to plot fitted trajectories for prototypical individuals. Even in a simple analysis like this, which involves just one dichotomous predictor, we find it invaluable to inspect prototypical trajectories visually. For this particular model, only two prototypes are possible: a program participant ($PROGRAM = 1$) and a nonparticipant ($PROGRAM = 0$). Substituting these values into equation (5) yields the predicted initial status and annual growth rates for each:

When $PROGRAM = 0$:

$$\hat{\pi}_{0i} = 107.84 + 6.85(0) = 107.84$$

$$\hat{\pi}_{1i} = -21.13 + 5.27(0) = -21.13$$

When $PROGRAM = 1$:

$$\hat{\pi}_{0i} = 107.84 + 6.85(1) = 114.69$$

$$\hat{\pi}_{1i} = -21.13 + 5.27(1) = -15.86 \quad (7)$$

We use these estimates to plot the fitted change trajectories in the right-hand panel of Figure 1. These plots reinforce the numeric conclusions just articulated. In comparison to nonparticipants, the average participant has a higher score at age 1 and a slower annual rate of decline.

Estimated variance components assess the amount of outcome variability left – at either level-1 or level-2 – after fitting the multilevel model. Because they are harder to interpret in absolute terms, many researchers use null-hypothesis tests, for at least they provide some benchmark for comparison. Some caution is necessary, however, because the null hypothesis is on the border of the parameter space (by definition, these components cannot be negative) and as a result, the asymptotic distributional properties that hold in simpler settings may not apply [9].

The level-1 residual variance, σ_e^2 , summarizes the population variability in an average person's outcome values around his or her own true change trajectory. Its estimate for these data is 74.24, a number that is difficult to evaluate on its own. Rejection of the associated null-hypothesis test (at the .001 level) suggests the existence of additional outcome variation at level-1 (within-person) that may be predictable. This suggests it might be profitable to add time-varying predictors to the level-1 model (such as the number of books in the home or the amount of parent-child interaction).

The level-2 variance components summarize the variability in change trajectories that remains after controlling for predictors (here, $PROGRAM$). Associated tests for these variance components evaluate whether there is any remaining *residual* outcome variation that could potentially be explained by other predictors. For these data, we reject only one of these null hypotheses (at the 0.001 level), for initial status, σ_0^2 . This again suggests the need for additional predictors, but because this is a level-2 variance component (describing residual variation in true initial status), we would consider both time-varying *and* time-invariant predictors to the model. Failure to reject the null hypothesis for σ_1^2 indicates that $PROGRAM$ explains all the potentially predictable variation between children in their true annual rates of change.

Finally turn to the level-2 covariance component, σ_{01} . Failure to reject this null hypothesis indicates that the intercepts and slopes of the individual true change trajectories are uncorrelated – that there is no association between true initial status and true annual rates of change (once the effects of $PROGRAM$ are removed). Were we to continue with model building, this result might lead us to drop the second level-2 residual, ζ_{1i} , from our model, for neither its variance nor covariance with ζ_{0i} , is significantly different from 0.

Postscript

Growth curve modeling offers empirical researchers a wealth of analytic opportunities. The method can accommodate any number of waves of data, the occasions of measurement need not be equally spaced, and different participants can have different data collection schedules. Individual change can be represented by a variety of substantively interesting trajectories, not only the linear functions presented here but also curvilinear and discontinuous functions. Not only can multiple predictors of change be included in a single analysis, simultaneous change across multiple domains (e.g., change in cognitive function and motor function) can be investigated simultaneously. Readers wishing to learn more about growth curve modeling should consult one of the recent books devoted to the topic [3, 4, 6, 8–10].

Guttman, Louise (Eliyahu)

Born: February 10, 1916, in Brooklyn, USA.

Died: October 25, 1987, in Minneapolis, USA.

‘Mathematics is contentless, and hence – by itself – not empirical science’: this encapsulates, in his own words, Guttman’s creed. In one of the paradoxes so prevalent in the social sciences, his striving to reveal the fundamental structures of social and psychological phenomena, their ‘content’, has tended to be eclipsed by his many contributions to statistical methodology, the ‘mathematics’ that Guttman always saw as a servant to the discovery of general laws, never an end in its own right. The approach to research that he called *Facet Theory*, which he spent his life developing, is a set of fundamental postulates that describes the interplay between the substantive ways of describing phenomena and the empirical observations of properties of their structures. He showed how this approach generates universally sound predictions, which he called ‘laws’. These are characterized by his ‘First Law of Attitude’:

If any two items are selected from the universe of attitude items towards a given object, and if the population observed is not selected artificially, then the population regressions between these two items will be monotone and with positive or zero sign.

This law summarizes a vast swathe of social science and makes redundant thousands of studies that have poorly defined items or confused methodologies. A similar ‘First Law of Intelligence’ has been hailed as one of the major contributions not only to our understanding of intelligence and how it varies between people but also how it is most appropriately defined.

Guttman completed his BA in 1936 and his MA in 1939 at the University of Minnesota, where his doctorate in social and psychological measurement was awarded in 1942. He had already published, at the age of 24, ‘A Theory and Method of Scale Construction’, describing an innovative approach to measuring attributes that came to bear his name [1]. At the time, it was not appreciated that this ‘Guttman Scale’ enshrined a radically new approach that bridged

the divide between qualitative and quantitative data, demonstrating how, as he later put it, ‘The form of data analysis is part of the hypothesis’. He spent the next half-century developing the implications of his precocious invention into a full-fledged framework for discovering the multidimensional structures of human phenomena [3].

His postgraduate research at The University of Chicago and later at Cornell University as World War II was breaking out gave him a role in a Research Branch of the US War Department, providing him with the starkest awareness of the practical potential of the social sciences. He took this commitment to make psychology and sociology of real significance when he moved to Jerusalem in 1947, setting up a Research Unit within the then Hagana, the Zionist underground army, making this surely the first illegal military group to have an active social research section.

With the establishment of the State of Israel, he converted his military unit into the highly respected Israel Institute of Applied Social Research, which he directed until his death. While being for most of his professional life a Professor at The Hebrew University of Jerusalem, he also always somehow managed to remain active in the United States, usually through visiting professorships, notably at Minnesota, Cornell, Harvard, and MIT. So that even though his Institute provided a crucial service to Israel (as it established itself through many wars with its neighbors) ranging from rapid opinion surveys on topics in the news to the basis for reforms in the civil service grading system, Guttman still contributed to a remarkably wide range of methodological innovations that enabled statistical procedures to be of a more scientific validity. The most notable of these was his discovery of the ‘radex’ as a generalization of factor analysis. This is a structure that combines both qualitative and quantitative facets revealed in data sets drawn from areas as diverse as personal values, intelligence, interpersonal relationships, and even the actions of serial killers [2].

His harnessing of mathematics, in particular, linear algebra, to many problems in multivariate statistics (see **Multivariate Analysis: Overview**) proved of particular value in the development of the computer programs that evolved along with his career. But it is fair to emphasize that his ideas were always pushing the limits of computing capability and it is only now that widely available systems have the

power to achieve what he was aiming for, a truly integrated relationship between statistical analysis and theory development.

He was awarded many honors, including The Rothschild Prize in the Social Sciences (1963), election as President of the Psychometric Society (1970), an Outstanding Achievement Award from the University of Minnesota (1974), The Israel Prize in the Social Sciences (1978), and The Educational Testing Service Measurement Award from Princeton (1984).

Those who knew him well remember him as a mild-mannered person who would not tolerate fools, of a scientific and mathematical integrity that was so impeccable it was easily interpreted as arrogance. An inspiration to his students and close colleagues, whose – always well-intentioned – incisive criticism left those who had contact with him changed for life (see [4] for more on his work).

Harmonic Mean

The harmonic mean $\bar{X}_h$ of a set of n numbers $X_1, X_2, \dots, X_n (i = 1, 2, \dots, n)$ is defined as

$$\bar{X}_h = \frac{n}{\sum_i \frac{1}{X_i}}. \quad (1)$$

In other words, the harmonic mean is the reciprocal of the mean of the reciprocals of the numbers. Note that the harmonic mean is only defined for sets of positive numbers.

As a simple illustration, we see that the harmonic mean of 20 and 25 is

$$\begin{aligned} \bar{X}_h &= \frac{2}{1/20 + 1/25} = \frac{2}{0.05 + 0.04} = \frac{2}{0.09} \\ &= 22.22 \text{ (to two decimal places)}. \end{aligned} \quad (2)$$

The harmonic mean is applicable in studies involving a between-subjects design but where there are unequal sample sizes in the different groups (unbalanced designs). One application is working out the statistical **power** of a test for a between-subjects t Test when the samples in the two groups are unequal [2]. The recommended sample size necessary to achieve power of 0.8 with an effect size of $d = 0.5$ (i.e., that the mean of the two groups differs by half a standard

deviation), using a two-tailed probability and an alpha level of 0.05 is 64 in each group, which would produce a total sample size of 128. When the sample sizes are unequal, then the equivalent of the sample size for each group required to attain the same level of statistical power is the harmonic mean. Suppose that one group had double the sample size of the other group, then, to achieve the same level of statistical power, the harmonic mean of the sample sizes would have to be 64. This means that the smaller group would require 48 members, while the larger group would need 96. Thus, the total sample size would be 144, which is an increase of 16 people over the design with equal numbers in each group (a balanced design).

A second example of the use of the harmonic mean is in **analysis of variance (ANOVA)** for unbalanced designs [1]. One way to deal with the problem is to treat all the groups as though they have the same sample size: the harmonic mean of the individual sample sizes.

Hawthorne Effect

The term *Hawthorne effect* has come to refer mistakenly to an increase in worker performance resulting merely from research or managerial attention to a work group. References to a Hawthorne effect in describing research have also come to connote flawed research. For example, when researchers obtrusively measure progress in implementing a health, educational, or social program, critics may raise questions about whether a Hawthorne effect may account for outcomes observed. Accordingly, understanding not only how the performance improvements observed in the Hawthorne study were produced but also of the design flaws in the original research are helpful for stimulating better worker performance and for conducting research that allows sound causal inferences.

Preliminary studies conducted at the Western Electric plant in the late 1920s briefly described by Rothlisberger and Dickson ([8, pp. 14–18], citing a brief nontechnical account, [9]) implied that the changes researchers made in illumination levels produced improvements in worker performance whether lighting was increased or decreased. A detailed account of these preliminary studies is not available. The preliminary studies led to a subsequent five-year program of research on industrial fatigue that is well reported. These studies were part of a larger inquiry about social relations in the workplace that broadly influenced the course of subsequent research and practice in industrial relations and industrial organizational psychology. Among the findings of the Hawthorne researchers about workplace social relations was the observation that social influences discouraging excess productivity can limit worker output.

In the well-documented relay-assembly study that was part of the Hawthorne research, the research participants were a group of five women who assembled electrical components (relays). Relay assembly was a repetitive task in which a worker selected parts, discarded flawed parts, and held pieces together while inserting screws. The five women in the study were located in a special room that was partitioned from an area in which a much larger group of about 100 assemblers worked.

The practice in the general relay-assembly room was to guarantee workers an hourly wage, but if the group produced a number of units with a piecework

value greater than the workers' aggregate guaranteed wages, the pay would be increased. For example, if the piecework value of relays assembled was 3% greater than the aggregate guaranteed wages of the 100 workers, then each worker would receive 103% of her guaranteed pay. Thus, the pay received in the general relay room was based on a large-group-contingency plan not expected to have much influence on productivity because reward is only tenuously contingent on individual performance [4]. Three key changes occurred in the experimental relay-assembly experiment. First, the five experimental women were moved to a separate room. Second, a running tally of each woman's production was made by means of an electronic counter, and the tally was available to the workers as they worked. Third, pay became contingent on the productivity of a small group of five people (rather than a large group of 100).

The researchers introduced additional changes over the course of the experiment. They increased scheduled rest periods. They also varied the food or beverages provided to the workers. And they experimented with shortening the workday and length of the workweek. The hourly production of the relay assemblers began to rise when the small group contingency pay plan was put in place, and with only occasional temporary downturns, production continued to rise over the course of the study [2, 3, 8].

Although a number of explanations of the increased productivity have been offered [1, 2, 10, 11], the most persuasive are those suggested by Parsons [7] and Gottfredson [3]. Rothlisberger and Dickson [8] had noted that the introduction near the beginning of the study of the small group contingency for pay seemed to lead to an increase in productivity, but they argued that this could not be responsible for the continuing rise in productivity over subsequent weeks. The researchers had selected experienced assemblers to participate in the experiment to rule out learning effects in what they viewed as a study in industrial fatigue, but they apparently overlooked the possibility that even experienced assemblers could learn to produce more relays per hour.

Parsons [7] persuasively argued for a learning explanation of the Hawthorne effect (*see Carry-over and Sequence Effects*). Basically, the provision of feedback and rewards contingent on performance led to learning and increased speed and accuracy in assembly. In addition, the separation of the workers

from the main group of assemblers and the use of small group contingencies may have stimulated peer influence to favor rather than limit productivity. If, as seems most likely, the learning interpretation is correct, a serious design flaw in the Hawthorne relay-assembler experiment was the failure to establish a performance baseline before varying rest periods and other working conditions presumed to be related to fatigue. Once reward for performance and feedback were both present, productivity began to increase and generally increased thereafter even during periods when other conditions were constant. For details, see accounts by Gottfredson and Parsons [3, 7]. Furthermore, observation logs imply that the workers set personal goals of improving their performance. For example, one assembler said, “I made 421 yesterday, and I’m going to make better today” [8, p. 74].

In contemporary perspective, the Hawthorne effect is understandable in terms of goal-setting theory [5, 6]. According to goal-setting theory, workers attend to feedback on performance when they adopt personal performance goals. Contingent rewards, goals set by workers, attention to information, and the removal of social obstacles to improved productivity led workers to learn to assemble relays faster – and to display their learning by producing more relays per hour. Gottfredson [3] has provided additional examples in which a similar process – a Hawthorne effect according to this understanding – is produced. Understanding the remarkable improvement in worker performance in the Hawthorne relay-assembly study in this way is important because it suggests how one obtains the ‘Hawthorne effect’ when improvements in worker performance are desired: remove obstacles to improvement, set goals, and provide feedback. Then if learning is possible, performance may improve.

What of the Hawthorne effect as research design flaw? There was a flaw in the relay-assembly study – the failure of the design to rule out learning as a rival

hypothesis to working conditions as an explanation for the changes in productivity observed. Designs that rule out this rival hypothesis, such as the establishment of an adequate baseline or the use of a randomly equivalent control group, are therefore often desirable in research.

Heritability

Before discussing what genetic heritability is, it is important to be clear about what it is not. For a binary trait, such as whether an individual has a disease, heritability is not the proportion of disease in the population attributable to, or caused by, genetic factors. For a continuous trait, genetic heritability is not a measure of the proportion of an individual's score attributable to genetic factors. Heritability is not about cause *per se*, but about the causes of variation in a trait across a particular population.

Definitions

Genetic heritability is defined for a quantitative trait. In general terms, it is the proportion of variation attributable to genetic factors. Following a genetic and environmental variance components approach, let Y have a mean μ and variance σ^2 , which can be partitioned into genetic and environmental components of variance, such as additive genetic variance σ_a^2 , dominance genetic variance σ_d^2 , common environmental variance σ_c^2 , individual specific environmental variance σ_e^2 , and so on (*see ACE Model*).

Genetic heritability in the narrow sense is defined as

$$\frac{\sigma_a^2}{\sigma^2}, \quad (1)$$

while genetic heritability in the broad sense is defined as

$$\frac{\sigma_g^2}{\sigma^2}, \quad (2)$$

where σ_g^2 includes all genetic components of variance, including perhaps components due to **epistasis** (gene–gene interactions; *see Genotype*) [3]. In addition to these random genetic effects, the total genetic variation could also include that variation explained when the effects of measured genetic markers are modeled as a fixed effect on the trait mean.

The concept of genetic heritability, which is really only defined in terms of variation in a quantitative trait, has been extended to cover categorical traits by reference to a genetic liability model (*see Liability Threshold Models*). It is assumed that there is an underlying, unmeasured continuous ‘liability’ scale divided into categories by ‘thresholds’. Under

the additional assumption that the liability follows a normal distribution, genetic and environmental components of variance are estimated from the pattern of associations in categorical traits measured in relatives. The genetic heritability of the categorical trait is then often defined as the genetic heritability of the presumed liability (latent variable), according to (1) and (2).

Comments

There is no unique value of the genetic heritability of a characteristic. Heritability varies according to which factors are taken into account in specifying both the mean and the total variance of the population under consideration. That is to say, it is dependent upon modeling of the mean, and of the genetic and environmental variances and covariances. Moreover, the total variance and the variance components themselves may not be constants, even in a given population. For example, even if the genetic variance actually increased with age, the genetic heritability would decrease with age if the variation in nongenetic factors increased with age more rapidly. That is to say, genetic heritability and genetic variance can give conflicting impressions of the ‘strength of genetic factors’.

Genetic heritability will also vary from population to population. For example, even if the heritability of a characteristic in one population is high, it may be quite different in another population in which there is a different distribution of environmental influences.

Measurement error in a trait poses an upper limit on its genetic heritability. Therefore, traits measured with large measurement error cannot have substantial genetic heritabilities, even if variation about the mean is completely independent of environmental factors. By the definitions above, one can increase the genetic heritability of a trait by measuring it more precisely, for example, by taking repeat measurements and averaging, although strictly speaking the definition of the trait has been changed also. A trait that is measured poorly (in the sense of having low reliability) will inevitably have a low heritability because much of the total variance will be due to measurement error (σ_e^2). However, a trait with relatively little measurement error will have a high heritability if all the nongenetic factors are known and taken into account in the modeling of the mean.

2 Heritability

Fisher [1] recognized these problems and noted that

whereas ... the numerator has a simple genetic meaning, the denominator is the total variance due to errors of measurement [including] those due to uncontrolled, but potentially controllable environmental variation. It also, of course contains the genetic variance ... Obviously, the information contained in [the genetic variance] is largely jettisoned when its actual value is forgotten, and it is only reported as a ratio to this hotch-potch of a denominator.

Historically, other quantities have also been termed *heritabilities*, but it is not clear what parameter is being estimated, for example, Holzinger's $H = (r_{MZ} - r_{DZ})$ (the correlation between monozygotic twins minus the correlation between dizygotic twins) [2], Nichol's $HR = 2(r_{MZ} - r_{DZ})/r_{MZ}$ [5], the E of Neel & Schull [4] based on twin data alone, and Vandenberg's $F = 1/[1 - (\sigma_a^2/\sigma^2)]$ [6]. Furthermore, the statistical properties of these estimators do not appear to have been studied.

Heritability: Overview

The contributor to this essay consulted a resource given to him when he entered graduate school for a definition of the term heritability. The resource aspired to include ‘all terms frequently used by psychologists’, and it purported to be a ‘comprehensive dictionary’ of psychological terms [2]. Heritability does not appear in the dictionary. But, under the entry ‘hereditarianism’, that 1958 dictionary asked the question: ‘To what extent do genetic factors influence behavior?’ And, that is the very question addressed by the statistical estimate we now call heritability. Once omitted from a comprehensive dictionary of psychological terms, heritability now occupies a full chapter in most introductory psychology textbooks, appears frequently in news releases on research in behavior and medicine, and yields dozens, perhaps hundreds, of links in an Internet search: heritability has become a central concept in behavioral science.

A statistical measure originating in quantitative genetics, heritability is an estimate of the contribution of genetic differences to the differences observed in a measured variable (e.g., some dimension of behavior) in a given population at a given time. Estimates of heritability have been obtained from many species, for many diverse behaviors, in samples of relatives from many human cultures, and across the human lifespan from infancy to senescence. Together, the accumulated heritability estimates offer compelling evidence of the importance of genetic influences on behavior, and, as a result, the concept of heritability has assumed critical importance in understanding the meaning and development of individual differences in behavioral development. Efforts to obtain heritability estimates have generated volumes of research over the past four decades, and, initially, these estimates aroused controversy and misunderstanding as heritability research within quantitative genetic studies of plants and animals was broadened to widespread application in human behavior genetics. Within the fields of behavioral and psychiatric genetics, the fields whose practitioners have developed the analytic tools to yield estimates of heritability for complex human behaviors, the term assumed new meaning: throughout the 1960s and 1970s, the mere demonstration of nonzero heritability for diverse behaviors was a goal, often *the* research goal; behavioral geneticists sought to show that the name of their discipline was not an

oxymoron. But by the 1980s and 1990s, the cumulative results of heritability research convinced most behavioral scientists that heritability estimates for nearly all behaviors are nonzero, and current research focuses much less on demonstrating heritability, and much more on how it is modulated by changing environments, or gene-environment interaction.

Heritability has two definitions. As a statistical estimate, the term is defined as the proportion of observable or phenotypic variance attributable to underlying genetic variation (*see* **Genotype**). And within that definition, narrow heritability considers **additive genetic variance** only, so the term is defined as the ratio of variance due to additive genes to the total variance observed in the behavior under study. That definition originated in selective breeding studies of animals, and it remains important in those applications, where the question addressed is the extent to which offspring will ‘breed true’. In contrast, a broad-sense statistical definition of heritability considers it to be the ratio of observed differences to *all* sources of genetic variation, additive or nonadditive (*see* **ACE Model**). Behavioral scientists are less interested in breeding coefficients than in the extent to which individual differences in behavior are due to genetic differences, whatever their source. So it is this second definition that captures the usual meaning of the concept for behavioral science: heritability defines the extent to which individual differences in genes contribute to individual differences in observable behavior. Some important caveats: Heritability is an abstract concept. More importantly, it is a population concept. It does not describe individuals, but rather the underlying differences between people. It is an estimate, typically made from the resemblance observed among relatives, and, as is true of any statistical estimate, heritability estimates include errors of estimation as a function of (genetic) effect size, the size and representativeness of the studied sample of relatives, and the precision with which the studied outcome can be measured. For some outcomes, such as adult height, the genetic effect is very large, and the outcome can be measured with great precision. For others, such as prosocial behavior in childhood, the genetic effect may be more modest, and the measurement much more uncertain. Heritability estimates vary, also, with age and circumstance, because the magnitude of genetic variance may dramatically change during development and across environments.

2 Heritability: Overview

Heritability is a relative concept in another sense: it is derived from the comparative similarity of relatives who differ in their shared genes. The most common approach is to compare samples of the two kinds of twins. Monozygotic (MZ) twins derive from a single zygote, and, barring rare events, they share all their genes identical-by-descent. Dizygotic (DZ) twins, like ordinary siblings, arise from two zygotes created by the same parents, and share, on average, one-half of their segregating genes. If, in a large and representative sample of twins, behavioral similarity of DZ twins approaches that found for MZ twins, genetic factors play little role in creating individual differences in that behavior; heritability is negligible, and the observed behavioral differences must be due to differences in environments shared by both kinds of cotwins in their homes, schools, and neighborhoods. Conversely, if the observed correlation of MZ cotwins doubles that found for DZ twins – a difference in resemblance that parallels their differences in genetic similarity – heritability must be nonzero (*see Twin Designs*). We can extend the informational yield found in contrasts of the two kinds of twins by adding additional members of the families of the twins. Consider, for example, children in families of monozygotic twin parents. Children in each of the two nuclear families derive half their genes from a twin parent, and those genes are identical with the genes of the parent's twin sister or brother, the children's 'twin aunt' or 'twin uncle'. Because the children and the twin aunt or uncle do not live in the same household, their resemblance cannot be due to household environment. And because the MZ twin parents have identical sets of nuclear genes, their children are genetically related to one another as half-siblings; socially, they are reared as cousins in separate homes. Thus, MZ twin families yield informative relationships ranging from those who share all their genes (MZ parents) to those sharing one-half (siblings in each nuclear family; parents and their children; children and their twin aunt/uncle), one-quarter (the cousins who are half-siblings), or zero (children and their spousal aunt or uncle).

We studied two measures in families of MZ twin parents: one, a behavioral measure of nonverbal intelligence, the other, the sum of fingerprint ridge counts, a morphological measure known to be highly heritable. For both measures, familial resemblance appeared to be a direct function of shared genes [8]. But, there was a substantial difference in

the magnitude of heritability estimates found for the two measures, ranging from 0.68 to 0.92 for total ridge count, but much less, 0.40 to 0.54 for the measure of nonverbal intelligence. That finding is consistent with research on many species [5]: behavioral traits exhibit moderate levels of heritability, much less than what is found for morphological and physiological traits, but greater than is found for life-history characteristics. The heritability estimates illustrated from families of MZ twins date from a 1979 study. They were derived from coefficients of correlation and regression among different groups of relatives in these families; interpretation of those estimates was confounded by the imprecision of the coefficients on which they were based, and the fact that effects of common environment were ignored. Now, 25 years later, estimates of heritability typically include 95% confidence intervals, and they are derived from robust analytic models. The estimates are derived from models fit to data from sets of relatives, and heritability is documented by showing that models that set it to zero result in a significantly poorer fit of the model to the observed data. Effects of common environments are routinely tested in an analogous manner. Analytic techniques for estimating heritability are now much more rigorous, and allow for tests of differential heritability in males and females. But they remain estimates derived from the relative resemblance of relatives who differ in the proportion of their shared genes.

Why do people differ? Why do brothers and sisters, growing up together, sharing half their genes and many of their formative experiences, turn out differently – in their interests, aptitudes, lifestyles? The classic debate was framed as nature *versus* nurture, as though genetic dispositions and experiential histories were somehow oppositional, and as though a static decomposition of genetic and environmental factors could adequately capture a child's developmental trajectory. But, clearly, this is simplification. If all environmental differences were removed in a population, such that all environments offered the same opportunities and incentives for acquisition of cognitive skills (and if all tests were perfectly reliable), people with the same genes would obtain the same aptitude test scores. If, conversely, the environments people experienced were very different for reasons independent of their genetic differences, heritability would be negligible. High heritability estimates do not elucidate *how* genetic differences effect differences in

behavioral outcomes, and it seems likely that many, perhaps most, gene effects on behavior are largely indirect, influencing the trait-relevant environment to which people are exposed.

Much recent research in the fields of behavioral and psychiatric genetics demonstrate substantial gene by environment interaction. Such research makes it increasingly apparent that the meaning of heritability depends on the circumstances in which it is assessed. Recent data suggest that it is nonsensical to conceptualize 'the heritability' of a complex behavioral trait, as if it were fixed and stable over time and environments. Across different environments, the modulation of genetic effects on adolescent substance use ranges as much as five or six fold, even when those environments are crudely differentiated as rural versus urban residential communities [1, 7], or religious versus secular households [4]. Similarly, heritability estimates for tobacco consumption vary dramatically for younger and older cohorts of twin sisters [3]. Such demonstrations suggest that genetic factors play much more of a role in adolescent alcohol use in environments where alcohol is easily accessed and community surveillance is reduced. And, similarly, as social restrictions on smoking have relaxed across generations, heritable influences have increased. Equally dramatic modulation of genetic effects by environmental variation is evident in effects of differences in socioeconomic status on the heritability of children's IQ [10].

In recent years, **twin studies** have almost monotonously demonstrated that estimates of heritable variance are nonzero across all domains of individual behavioral variation that can be reliably assessed. These estimates are often modest in magnitude, and, perhaps more surprisingly, quite uniform across different behavioral traits. But if heritability is so ubiquitous, what consequences does it have for scientific understanding of behavioral development?

All human behaviors are, to some degree, heritable, but that cannot be taken as evidence that the complexity of human behavior can be reduced to relatively simple genetic mechanisms [9]. Confounding heritability with strong biological determinism is an error. An example is criminality; like nearly all behaviors, criminality is to some degree heritable. There is nothing surprising, and nothing morally repugnant in the notion that not all children have

equal likelihood of becoming a criminal. To suggest that, however, is neither to suggest that specific biological mechanisms for criminality are known, nor even that they exist. All behavior is biological and genetic, but some behaviors are biological in a stronger sense than others, and some behaviors are genetic in a stronger sense than others [9]. Criminality is, in part, heritable, but unnecessary mischief is caused by reference to genes 'for' criminality – or any similar behavioral outcome. We inherit dispositions, not destinies [6]. Heritability is an important concept, but it is important to understand what it is. And what it is not.

Heteroscedasticity and Complex Variation

Introduction

Consider the simple linear regression model with normally distributed residuals

$$y_i = \beta_0 + \beta_1 x_i + e_i \quad e_i \sim N(0, \sigma_e^2) \quad (1)$$

where β_0 , β_1 are the intercept and slope parameters respectively, i indexes the observation, and e_i is an error term (*see Multiple Linear Regression*). In standard applications, such a model for a data set typically would be elaborated by adding further continuous or categorical explanatory variables and interactions until a suitable model describing the observed data is found (*see Model Selection*). A common diagnostic procedure is to study whether the constant residual variance (homoscedasticity) assumption in (1) is satisfied. If not, a variety of actions have been suggested in the literature, most of them concerned with finding a suitable nonlinear transformation of the response variable so that the homoscedasticity assumption is more closely approximated (*see Transformation*). In some cases, however, this may not be possible, and it will also in general change the nature of any regression relationship. An alternative is to attempt to model the heteroscedasticity explicitly, as a function of explanatory variables. For example, for many kinds of behavioral and social variables males have a larger variance than females, and rather than attempting to find a transformation to equalize these variances, which would in this case be rather difficult, we could fit a model that had separate variance parameters for each gender. This would have the advantage not only of a better fitting model, but also of providing information about variance differences that is potentially of interest in its own right.

This article discusses general procedures for modeling the variance as a function of explanatory variables. It shows how efficient estimates can be obtained and indicates how to extend the case of linear models such as (1) to handle multilevel data (*see Linear Multilevel Models*) [2]. We will first describe, through a data example using a simple linear model, a model fitting separate gender variances and then discuss general procedures.

An Example Data Set of Examination Scores

The data have been selected from a very much larger data set of examination results from six inner London Education Authorities (school boards). A key aim of the original analysis was to establish whether some schools were more ‘effective’ than others in promoting students’ learning and development, taking account of variations in the characteristics of students when they started Secondary school. For a full account of that analysis, see Goldstein et al. [5].

The variables we shall be using are an approximately normally distributed examination score for 16-year-olds as the response variable, with a standardized reading test score for the same students at age 11 and gender as the explanatory variables.

The means and variances for boys and girls are given in Table 1.

We observe, as expected, that the variance for girls is lower than for the boys.

We first fit a simple model which has a separate mean for boys and girls and which we write as

$$y_i = \beta_1 x_{1i} + \beta_2 x_{2i} + e_i \quad e_i \sim N(0, \sigma_e^2)$$

$$x_{1i} = 1 \text{ if a boy, } 0 \text{ if a girl, } x_{2i} = 1 - x_{1i} \quad (2)$$

There is no intercept in this model since we have a dummy variable for both boys and girls. Note that these data in fact have a two-level structure with significant variation between schools. Nevertheless, for illustrative purposes here we ignore that, but see Browne et al. [1] for a full multilevel analysis of this data set.

If we fit this model to the data using ordinary least squares (OLS) regression (*see Least Squares Estimation; Multiple Linear Regression*), we obtain the estimates in Table 2.

Note that the fixed coefficient estimates are the same as the means in Table 1, so that in this simple case the estimates of the means do not depend on the homoscedasticity assumption. We refer to the explanatory variable coefficients as ‘fixed’ since they

Table 1 Exam scores by gender

	Boy	Girl	Total
N	1623	2436	4059
Mean	−0.140	0.093	−0.000114
Variance	1.051	0.940	0.99

2 Heteroscedasticity and Complex Variation

Table 2 OLS estimates from separate gender means model (2)

	Coefficient	Standard error
<i>Fixed</i>		
Boy (β_1)	-0.140	0.024
Girl (β_2)	0.093	0.032
<i>Random</i>		
Residual variance (σ_e^2)	0.99	0.023
-2 log-likelihood	11455.7	

have a fixed underlying population value, and the residual variance is under the heading ‘random’ since it is associated with the random part of the model (residual term).

Modeling Separate Variances

Now let us extend (2) to incorporate separate variances for boys and girls. We write

$$\begin{aligned}
 y_i &= \beta_1 x_{1i} + \beta_2 x_{2i} + e_{1i} x_{1i} + e_{2i} x_{2i} \\
 e_{1i} &\sim N(0, \sigma_{e1}^2), \quad e_{2i} \sim N(0, \sigma_{e2}^2) \\
 x_{1i} &= 1 \text{ if a boy, } 0 \text{ if a girl, } x_{2i} = 1 - x_{1i} \quad (3)
 \end{aligned}$$

so that we have separate residuals, with their own variances for boys and girls. Fitting this model, using the software package MLwiN [6], we obtain the results in Table 3.

We obtain, of course, the same values as in Table 1 since this model is just fitting a separate mean and variance for each gender. (Strictly speaking they will not be exactly identical because we have used **maximum likelihood estimation** for our model estimates, whereas Table 1 uses unbiased estimates for the variances; if restricted maximum likelihood (REML) model estimates are used, then they will be

Table 3 Estimates from separate gender means model (3)

	Coefficient	Standard error
<i>Fixed</i>		
Boy (β_1)	-0.140	0.025
Girl (β_2)	0.093	0.020
<i>Random</i>		
Residual variance Boys (σ_{e1}^2)	1.051	0.037
Residual variance Girls (σ_{e2}^2)	0.940	0.027
-2 log-likelihood	11449.5	

identical (*see Maximum Likelihood Estimation*)). Note that the difference in the -2 log-likelihood values is 6.2, which judged against a chi squared distribution on 1 degree of freedom (because we are adding just 1 parameter to the model) is significant at approximately the 1% level.

Now let us rewrite (3) in a form that will allow us to generalize to more complex variance functions.

$$\begin{aligned}
 y_i &= \beta_0 + \beta_1 x_{1i} + e_i \\
 e_i &= e_{0i} + e_{1i} x_{1i} \\
 \text{var}(e_i) &= \sigma_{e0}^2 + 2\sigma_{e01} x_{1i} + \sigma_{e1}^2 x_{1i}^2, \quad \sigma_{e1}^2 \equiv 0 \\
 x_{1i} &= 1 \text{ if a boy, } 0 \text{ if a girl} \quad (4)
 \end{aligned}$$

Model (4) is equivalent to (3) with

$$\begin{aligned}
 \beta_2^* &\equiv \beta_0, \quad \beta_1^* \equiv \beta_0 + \beta_1 \\
 \sigma_{e2}^{2*} &\equiv \sigma_{e0}^2, \quad \sigma_{e1}^{2*} \equiv \sigma_{e0}^2 + 2\sigma_{e01} \quad (5)
 \end{aligned}$$

where the * superscript refers to the parameters in (3).

In (4), for convenience, we have used a standard notation for variances and the term σ_{e01} is written as if it were a covariance term. We have written the residual variance in (4) as $\text{var}(e_i) = \sigma_{e0}^2 + 2\sigma_{e01} x_{1i} + \sigma_{e1}^2 x_{1i}^2$, $\sigma_{e1}^2 \equiv 0$, which implies a covariance matrix with one of the variances equal to zero but a nonzero covariance. Such a formulation is not useful and the variance in (4) should be thought of simply as a reparameterization of the residual variance as a function of gender. The notation in (4) in fact derives from that used in the general multilevel case [2], and in the next section we shall move to a more straightforward notation that avoids any possible confusion with covariance matrices.

Modeling the Variance in General

Suppose now that instead of gender the explanatory variable in (4) is continuous, for example, the reading test score in our data set, which we will now denote by x_{3i} . We can now write a slightly extended form of (4) as

$$\begin{aligned}
 y_i &= \beta_0 + \beta_3 x_{3i} + e_i \\
 e_i &= e_{0i} + e_{3i} x_{3i} \\
 \text{var}(e_i) &= \sigma_{e0}^2 + 2\sigma_{e03} x_{3i} + \sigma_{e3}^2 x_{3i}^2 \quad (6)
 \end{aligned}$$

Table 4 Estimates from fitting reading score as an explanatory variable with a quadratic variance function

	Coefficient	Standard error
<i>Fixed</i>		
Intercept (β_0)	-0.002	
Reading (β_3)	0.596	0.013
<i>Random</i>		
Intercept variance (σ_{e0}^2)	0.638	0.017
Covariance (σ_{e03})	0.002	0.007
Reading variance (σ_{e3}^2)	0.010	0.011
-2 log-likelihood	9759.6	

This time we can allow the variance to be a quadratic function of the reading score; in the case of gender, since there are really only two parameters (variances) one of the parameters in the variance function (σ_{e1}^2) was redundant. If we fit (6), we obtain the results in Table 4.

The deviance (-2 log-likelihood) for a model that assumes a simple residual variance is 9760.5, so that there is no evidence here that complex variation exists in terms of the reading score. This is also indicated by the standard errors for the random parameters, although care should be taken in interpreting these (and more elaborate Wald tests) using Normal theory since the distribution of variance estimates will often be far from Normal.

Model (6) can be extended by introducing several explanatory variables with 'random coefficients' e_{hi} . Thus, we could have a model where the variance is a function of gender (with x_{2i} as the dummy variable for a girl) and reading score, that is,

$$y_i = \beta_0 + \beta_2 x_{2i} + \beta_3 x_{3i} + e_i$$

$$\text{var}(e_i) = \sigma_{e_i}^2 = \alpha_0 + \alpha_2 x_{2i} + \alpha_3 x_{3i} \quad (7)$$

We have changed the notation here so that the residual variance is modeled simply as a linear function of explanatory variables (Table 5).

The addition of the gender term in the variance is associated only with a small reduction in deviance (1.6 with 1 degree of freedom), so that including the reading score as an explanatory variable in the model appears to remove the heterogeneous variation associated with gender. Before we come to such a conclusion, however, we look at a more elaborate model where we allow for the variance to depend on the interaction between gender and the reading score,

Table 5 Estimates from fitting reading score and gender (girl = 1) as explanatory variables with linear variance function

	Coefficient	Standard error
<i>Fixed</i>		
Intercept (β_0)	-0.103	
Girl (β_2)	0.170	0.026
Reading (β_3)	0.590	0.013
<i>Random</i>		
Intercept (α_0)	0.665	0.023
Girl (α_2)	-0.038	0.030
Reading (α_3)	0.006	0.014
-2 log-likelihood	9715.3	

that is,

$$y_i = \beta_0 + \beta_2 x_{2i} + \beta_3 x_{3i} + e_i$$

$$\text{var}(e_i) = \sigma_{e_i}^2 = \alpha_0 + \alpha_2 x_{2i} + \alpha_3 x_{3i} + \alpha_4 x_{2i} x_{3i} \quad (8)$$

Table 6 shows that the fixed effects are effectively unchanged after fitting the interaction term, but that the latter is significant with a reduction in deviance of 6.2 with 1 degree of freedom. The variance function for boys is given by $0.661 - 0.040x_3$ and for girls by $0.627 + 0.032x_3$. In other words, the residual variance decreases with an increasing reading score for boys but increases for girls, and is the same for boys and girls at a reading score of about 0.5 standardized units. Thus, the original finding that boys have more variability than girls needs to be modified: initially low achieving boys (in terms of reading) have higher variance, but the girls have higher variance if they are initially high achievers. It is interesting to note that if we fit an interaction term between reading and gender in the fixed part of the model, we obtain a very small and nonsignificant coefficient whose inclusion does not affect the estimates for the remaining parameters. This term therefore, is omitted from Table 6.

One potential difficulty with linear models for the variance is that they have no constraint that requires them to be positive, and in some data sets the function may become negative within the range of the data or provide negative variance predictions that are unreasonable outside the range. An alternative formulation that avoids this difficulty is to formulate a nonlinear model, for example, for the logarithm of the variance having the general

4 Heteroscedasticity and Complex Variation

Table 6 Estimates from fitting reading score and gender (girl = 1) as explanatory variables with linear variance function including interaction

	Coefficient	Standard error
<i>Fixed</i>		
Intercept (β_0)	-0.103	
Girl (β_2)	0.170	0.026
Reading (β_3)	0.590	0.013
<i>Random</i>		
Intercept (α_0)	0.661	0.023
Girl (α_2)	-0.034	0.030
Reading (α_3)	-0.040	0.022
Interaction (α_4)	0.072	0.028
-2 log-likelihood	9709.1	

form

$$\log[\text{var}(e_i)] = \sum_h \alpha_h x_{hi}, \quad x_{0i} \equiv 1 \quad (9)$$

We shall look at estimation algorithms suitable for either the linear or nonlinear formulations below.

Covariance Modeling and Multilevel Structures

Consider the repeated measures model where the response is, for example, a growth measure at successive occasions on a sample of individuals as a polynomial function of time (t)

$$y_{ij} = \sum_{h=0}^p \beta_h t_{ij}^h + e_{ij}$$

$$\text{cov}(\mathbf{e}_j) = \Omega_e \quad \mathbf{e}_j = \{e_{ij}\} \quad (10)$$

where $\mathbf{e}_j$ is the vector of residuals for the j th individual and i indexes the occasion. The residual covariance matrix between measurements at different occasions (Ω_e) is nondiagonal since the same individuals are measured at each occasion and typically there would be a relatively large between-individual variation. The covariance between the residuals, however, might be expected to vary as a function of their distances apart so that a simple model might be as follows

$$\text{cov}(e_{tj}, e_{t-s,j}) = \sigma_e^2 \exp(-\alpha s) \quad (11)$$

which resolves to a first-order autoregressive structure (see **Time Series Analysis**) where the time intervals are equal.

The standard formulation for a repeated measures model is as a two-level structure where individual random effects are included to account for the covariance structure with correlated residuals. A simple such model with a random intercept u_{0j} and random ‘slope’ u_{1j} can be written as follows

$$y_{ij} = \sum_{h=0}^p \beta_h t_{ij}^h + u_{0j} + u_{1j} t_{ij} + e_{ij}$$

$$\text{cov}(\mathbf{e}_j) = \sigma_e^2 I, \quad \text{cov}(\mathbf{u}_j) = \Omega_u, \quad \mathbf{u}_j = \begin{pmatrix} u_{0j} \\ u_{1j} \end{pmatrix} \quad (12)$$

This model incorporates the standard assumption that the covariance matrix of the level 1 residuals is diagonal, but we can allow it to have a more complex structure as in (11). In general, we can fit complex variance and covariance structures to the level 1 residual terms in any multilevel model. Furthermore, we can fit such structures at any level of a data hierarchy. A general discussion can be found in Goldstein [2, Chapter 3] and an application modeling the level 2 variance in a multilevel generalized linear model (see **Generalized Linear Mixed Models**) is given by Goldstein and Noden [4]; in the case of generalized linear models, the level 1 variance is heterogeneous by virtue of its dependence on the linear part of the model through the (nonlinear) link function.

Estimation

For normally distributed variables, the likelihood equations can be solved, iteratively, in a variety of ways. Goldstein et al. [3] describe an iterative generalized least squares procedure (see **Least Squares Estimation**) that will handle either linear models such as (7) or nonlinear ones such as (9) for both variances and covariances. Bayesian estimation can be carried out readily using Monte Carlo Markov Chain (MCMC) methods (see **Markov Chain Monte Carlo and Bayesian Statistics**), and a detailed comparison of likelihood and Bayesian estimation for models with complex variance structures is given in Browne et al. [1]. These authors also compare the fitting of linear and loglinear models for the variance.

Conclusions

This article has shown how to specify and fit a model that expresses the residual variance in a linear

model as a function of explanatory variables. These variables may or may not also enter the fixed, regression part of the model. It indicates how this can be extended to the case of multilevel models and to the general modeling of a covariance matrix. The example chosen shows how such models can uncover differences between groups and according to the values of a continuous variable. The finding that an interaction exists in the model for the variance underlines the need to apply considerations of model adequacy and fit for the variance modeling. The relationships exposed by modeling the variance will often be of interest in their own right, as well as better specifying the model under consideration.

Heuristics

Heuristic comes from the Greek *heuriskein* meaning to find, hence *eureka* meaning I found it (out). Since its first use in English during the early 1800s, the term has acquired a range of meanings. For instance, in his Nobel prize-winning paper published in 1905 ('On a heuristic point of view concerning the generation and transformation of light'), Albert Einstein used the term to indicate that his view served to find out or to discover something [2]. Such a heuristic view may yield an incomplete and unconfirmed, eventually even false, but nonetheless useful picture. For the Gestalt psychologists who conceptualized thinking as an interaction between external problem structure and inner processes, heuristics (e.g., inspecting the problem, analyzing the conflict, the situation, the materials, and the goal) served the purpose of guiding the search for information in the environment and of restructuring the problem by internal processes [1]. In the 1950s and 60s, Herbert Simon and Allen Newell, two pioneers of Artificial Intelligence and cognitive psychology, used the term to refer to methods for finding solutions to problems. In formalized computer programs (e.g., the General Problem Solver), they implemented heuristics, for instance, the means-end analysis, which tried to set subgoals and to find

operations that finally reduced the distance between the current state and the desired goal state [5]. With the advent of information theory in cognitive psychology, the term heuristic came to mean a useful shortcut, an approximation, or a rule of thumb for searching through a space of possible solutions. Two prominent research programs in which heuristics play a key role are the *heuristics-and-biases program* [4] and the program of *simple heuristics* (often also referred to as **heuristics**, fast and frugal) [3].

Heuristics: Fast and Frugal

To understand what fast and frugal **heuristics** are, it is helpful first of all to shed some light on the notion of *bounded rationality*, a term that has been coined by Herbert Simon [11]. In contrast to models that aim at finding the optimal solution to a problem at hand, models of bounded rationality take into account that humans often have only limited information, time, and computational capacities when making judgments or decisions. Given these constraints, the optimal solution is often unattainable. Moreover, many problems (e.g., chess) are too complex for the optimal solution to be found within a reasonable amount of time, even if all the relevant knowledge is available (i.e., all the rules and the positions of all the figures on the chess board are known) and the most powerful computers are used. Models of bounded rationality specify the (cognitive) processes that lead to a *satisficing* solution to a given problem, that is, to a solution that is both *satisfying* and *sufficing*.

Fast and frugal heuristics are such models of bounded rationality [4, 6]. They are task-specific, that is, they are designed to solve a particular task (e.g., choice, numerical estimation, categorization), but cannot solve tasks that they are not designed for – just like a hammer, which is designed to hammer nails but is useless for sawing a board. In fact, this task-specificity is key to the notion of the *adaptive toolbox* [5], the collection of heuristics that has evolved and can be used by the human mind.

Although fast and frugal heuristics differ with respect to the tasks they are designed to solve, they share the same guiding construction principles. In particular, they are composed of *building blocks*, which specify how information is searched for (*search rule*), when information search is stopped (*stopping rule*), and how a decision is made based on the information acquired (*decision rule*). These heuristics are fast for two reasons. First, they do not integrate the acquired information in a complex and time-consuming way. In this respect, many heuristics of the adaptive toolbox are as simple as possible because they do not combine pieces of information at all; instead, the decision is based on just one single reason (*one-reason decision making*). Secondly, they are fast as a consequence of being frugal, that

is, they stop searching for further information early in the process of information acquisition.

Fast and frugal heuristics are ecologically rational. In the present context, the notion of *ecological rationality* has two meanings. First, the performance of a heuristic is not evaluated against a norm, be it a norm from probability theory (*see Bayesian Statistics; Decision Making Strategies*) or logic (e.g., the *conjunction rule*, according to which the probability that an object belongs to both classes A and B cannot exceed the probability of belonging to class A). Rather, its performance is evaluated against a criterion that exists in the environment (i.e., in the ecology). This implies that (most) fast and frugal heuristics have been designed to make inferences about objective states of the world rather than to develop subjective preferences that reflect an individual's utilities. For instance, the QuickEst heuristic [8] makes inferences about the numerical values of objects (e.g., number of inhabitants of cities), and is evaluated by comparing estimated and true values. Secondly, a heuristic is ecologically rational to the extent that its building blocks reflect the structure of information in the environment. This fit of a heuristic to the environment in which it is evaluated is an important aspect of fast and frugal heuristics, which gave rise to a series of studies and important insights [13].

Studies on fast and frugal heuristics include (a) computer simulations to explore the performance of the heuristics in a given environment, in particular, in real-world environments (e.g., [1]), (b) the use of mathematical or analytical methods to explore when and why they perform as well as they do (eventually supported by simulations, in particular, in artificially created environments in which information structures are systematically varied) (e.g., [9]), and (c) experimental and observational studies to explore whether and when people actually use these heuristics (e.g., [10]). In the remainder of this entry, two heuristics (including their ecological rationality and the empirical evidence) are briefly introduced.

The Recognition Heuristic. Most people would agree that it is usually better to have more information than to have less. There are, however, situations in which partial ignorance is informative, which the recognition heuristic exploits. Consider the following question: Which city has more inhabitants, San

2 Heuristics: Fast and Frugal

Antonio, or San Diego? If you have grown up in the United States, you probably have a considerable amount of knowledge about both cities, and should do far better than chance when comparing the cities with respect to their populations. Indeed, about two-thirds of University of Chicago undergraduates got this question right [7]. In contrast, German citizens' knowledge of the two cities is negligible. So how much worse will they perform? The amazing answer is that within a German sample of participants, 100% answered the question correctly [7]. How could this be? Most Germans might have heard of San Diego, but do not have any specific knowledge about it. Even worse, most have never even heard of San Antonio. However, this difference with respect to name recognition was sufficient to make an inference, namely that San Diego has more inhabitants. Their lack of knowledge allowed them to use the recognition heuristic, which, in general, says: *If one of two objects is recognized and the other not, then infer that the recognized object has the higher value with respect to the criterion* [7, p. 76]. The Chicago undergraduates could not use this heuristic, because they have heard of both cities – they knew too much.

The ecological rationality of the recognition heuristic lies in the positive correlation between criterion and recognition values of cities (if such a correlation were negative, the inference would have to go in the opposite direction). In the present case, the correlation is positive, because larger cities (as compared to smaller cities) are more likely to be mentioned in mediators such as newspapers, which, in turn, increases the likelihood that their names are recognized by a particular person. It should thus be clear that the recognition heuristic only works if recognition is correlated with the criterion. Examples include size of cities, length of rivers, or productivity of authors; in contrast, the heuristic will probably not work when, for instance, cities have to be compared with respect to their mayor's age or their altitude above sea level. By means of mathematical analysis, it is possible to specify the conditions in which a *less-is-more effect* can be obtained, that is, the maximum percentage of recognized objects in the reference class that would increase the performance in a complete paired comparison task and the point from which recognizing more objects would lead to a decrease in performance [7]. In a series of experiments in which participants had to compare cities

with respect to their number of inhabitants, it could be shown that they chose the object predicted by the recognition heuristic in more than 90% of the cases – this was even true in a study in which participants were taught knowledge contradicting recognition [7]. Moreover, the authors could empirically demonstrate two less-is-more effects, one in which participants performed better in a domain in which they recognized a lower percentage of objects, and another one in which performance decreased through successively working on the same questions (so that recognition of objects increased during the course of the experiment).

Take The Best. If both objects are recognized in a pair-comparison task (see **Bradley–Terry Model**), the recognition heuristic does not discriminate between them. A fast and frugal heuristic that could be used in such a case is Take The Best. For simplicity, it is assumed that all cues (i.e., predictors) are binary (positive or negative), with positive cue values indicating higher criterion values. Take The Best is a simple, lexicographic strategy that consists of the following building blocks:

- (0) *Recognition heuristic:* see above.
- (1) *Search rule:* If both objects are recognized, choose the cue with the highest validity (where validity is defined as the percentage of correct inferences among those pairs of objects in which the cue discriminates) among those that have not yet been considered for this task. Look up the cue values of the two objects.
- (2) *Stopping rule:* If one object has a positive value and the other does not (i.e., has either a negative or unknown value), then stop search and go on to Step 3. Otherwise go back to Step 1 and search for another cue. If no further cue is found, then guess.
- (3) *Decision rule:* Infer that the object with the positive cue value has the higher value on the criterion.

Note that Take The Best's search rule ignores cue dependencies and will therefore most likely not establish the optimal ordering. Further note that the stopping rule does not attempt to compute an optimal stopping point at which the costs of further search exceed its benefits. Rather, the motto of the heuristic is 'Take The Best, ignore the rest'. Finally

note that Take The Best uses ‘one-reason decision making’ because its decision rule does not weight and integrate information, but relies on one cue only.

Another heuristic that also employs one-reason decision making is the Minimalist. It is even simpler than Take The Best because it does not try to order cues by validity, but chooses them in random order. Its stopping rule and its decision rule are the same as those of Take The Best.

What price does one-reason decision making have to pay for being fast and frugal? How much more accurate are strategies that use all cues and combine them? To answer these questions, Czerlinski, Gigerenzer, and Goldstein [1] evaluated the performance of various strategies in 20 data sets containing real-world structures rather than convenient multivariate normal structures; they ranged from having 11 to 395 objects, and from 3 to 19 cues. The predicted criteria included demographic variables, such as mortality rates in US cities and population sizes of German cities; sociological variables, such as drop-out rates in Chicago public high schools; health variables, such as obesity at age 18; economic variables, such as selling prices of houses and professors’ salaries; and environmental variables, such as the amount of rainfall, ozone, and oxidants. In the tests, half of the objects from each environment were randomly drawn. From all possible pairs within this training set, the order of cues according to their validities was determined (Minimalist used the training set only to determine whether a positive cue value indicates a higher or lower criterion). Thereafter, performance was tested both on the training set (fitting) and on the other half of the objects (generalization). Two

linear models were introduced as competitors: **multiple linear regression** and a simple unit-weight linear model [2]. To determine which of two objects has the higher criterion value, multiple regression estimated the criterion of each object, and the unit-weight model simply added up the number of positive cue values.

Table 1 shows the counterintuitive results obtained by averaging across frugality and percentages of correct choices in each of the 20 different prediction problems. The two simple heuristics were most frugal: they looked up fewer than a third of the cues (on average, 2.2 and 2.4 as compared to 7.7). What about the accuracy? Multiple regression was the winner when the strategies were tested on the training set, that is, on the set in which their parameters were fitted. However, when it came to predictive accuracy, that is, to accuracy in the hold-out sample, the picture changed. Here, Take The Best was not only more frugal, but also more accurate than the two linear strategies (and even Minimalist, which looked up the fewest cues, did not perform too far behind the two linear strategies). This result may sound paradoxical because multiple regression processed all the information that Take The Best did and more. However, by being sensitive to many features of the data – for instance, by taking correlations between cues into account – multiple regression suffered from overfitting, especially with small data sets (*see Model Evaluation*). Take The Best, on the other hand, uses few cues. The first cues tend to be highly valid and, in general, they will remain so across different subsets of the same class of objects. The stability of highly valid cues is a main factor for the robustness of Take The Best, that is, its low danger of overfitting in cross-validation as well as in other

Table 1 Performance of two fast and frugal heuristics (Take The Best and Minimalist) and two linear models (multiple regression and a unit-weight linear model) across 20 data sets. *Frugality* denotes the average number of cue values looked up; *Fitting* and *Generalization* refer to the performance in the training set and the test set, respectively (see text). Adapted from Gigerenzer, G. & Todd, P.M., and the ABC Research Group. (1999). *Simple heuristics that make us smart*, Oxford University Press, New York [6]

Strategy	Frugality	Accuracy (% correct)	
		Fitting	Generalization
Take The Best	2.4	75	71
Minimalist	2.2	69	65
Multiple Regression	7.7	77	68
Unit-weight linear model	7.7	73	69

forms of incremental learning. Thus, Take The Best can have an advantage against more savvy strategies that capture more aspects of the data, when the task requires making out-of-sample predictions (for other aspects of Take The Best's ecological rationality, see [9]).

There is meanwhile much empirical evidence that people use fast and frugal heuristics, in particular, when under time pressure or when information is costly (for a review of empirical studies see [3]). For other fast and frugal heuristics beyond the two introduced above, for instance QuickEst (for numerical estimation), Categorization-by-elimination (for categorization), RAFT (Reconstruction After Feedback with Take The Best, for an application to a memory phenomenon, namely *the hindsight bias*), the gaze heuristics (for catching balls on the playground), or various simple rules for terminating search through sequentially presented options, see [3, 5, 6, 12, 13]; for a discussion of this research program, see the commentaries and the authors' reply following [12].

Hierarchical Clustering

Cluster analysis is a term for a group of multivariate methods that explore the similarities or differences between cases in order to find subgroups containing relatively homogenous cases (*see Cluster Analysis: Overview*). The cases may be, for example, patients with various symptoms, ideas arising from a focus group, clinics with different types of patient. There are two main types of cluster analysis: *optimization methods* that produce a single partition of the data (*see k-means Analysis*), usually into mutually exclusive (but possible overlapping) clusters, and *hierarchical clustering*, which is the subject of this article. Hierarchical clustering forms a nested series of mutually exclusive partitions or subgroups of the data, rather than a single partition. The process by which the series is formed is often displayed in a diagram known as a *dendrogram*. The investigator generally has to choose one of the partitions in the series as the ‘cluster solution’. Hierarchical clustering is possibly the most commonly applied type of cluster analysis and it is widely available in general statistical software packages.

Clusters are either successively divided, starting with a single cluster containing all individuals (*divisive clustering*) or they are successively merged, starting with n singleton clusters and ending with one large cluster containing all n individuals (*agglomerative clustering*). Both divisive and agglomerative techniques attempt to find the optimal step at each stage in the progressive subdivision or synthesis of the data. Divisions or fusions, once made, are irrevocable so that when an agglomerative algorithm has joined two individuals they cannot subsequently be separated, and when a divisive algorithm has made a split they cannot be reunited.

Proximities

Typically the process starts with a *proximity matrix* of the similarities or dissimilarities between all pairs of cases to be clustered (*see Proximity Measures*). The matrix may be derived from direct judgments: for example, in market research studies a number of subjects might be asked to assess the pairwise similarities of various foods using a visual analogue scale ranging from very dissimilar to very similar, their

average opinion giving a single value for each pair of foods. More commonly, however, the proximities are combined from similarities or differences defined on the basis of several different measurements, for example, saltiness, sweetness, sourness and so on.

The formula for combining similarities based on several variables depends on the type of data and the relative weight to be placed on different variables. For example binary data may be coded as series of 1s and 0s, denoting presence or absence of an attribute. In the case where each category is of equal weight, such as gender or white/nonwhite ethnic group, a *simple matching coefficient* (the proportion of matches between two individuals) could be used. However, if the attributes were the presence of various symptoms, proximity might be more appropriately measured using the asymmetric *Jaccard coefficient*, based on the proportion of matches where there is a positive match (i.e., ignoring joint negative matches). In genetics, binary matches may be assigned different weights depending on the part of the genetic sequence from which they arise. For continuous data, the *Euclidean distance* between individuals i and j , is often used:

$$s_{ij} = \left(\sum_{k=1}^p (x_{ik} - x_{jk})^2 \right)^{1/2}, \quad (1)$$

where p is the number of variables and x_{ik} is the value of the k th variable for case i . Applied to binary data it is the same as the simple matching coefficient. The following is another example of a measure for continuous data, the (range-scaled) *city block* measure:

$$s_{ij} = 1 - \sum_{k=1}^p \frac{|x_{ik} - x_{jk}|}{R_k}, \quad \text{where} \quad (2)$$

R_k is the range for the k th variable.

For data that contain both continuous and categorical variables, *Gower's coefficient* [6] has been proposed:

$$s_{ij} = \frac{\sum_{k=1}^p w_{ijk} s_{ijk}}{\sum_{k=1}^p w_{ijk}}, \quad (3)$$

where s_{ijk} is the similarity between the i th and j th individual as measured by the k th variable.

2 Hierarchical Clustering

For components of distance derived from binary or categorical data s_{ijk} takes the value of 1 for a complete match and 0 otherwise. For components derived from continuous data the range-scaled city block measure mentioned above is suggested. The value of w_{ijk} can be set to 0 or 1 depending on the whether the comparison is valid (for example, with a binary variable it can be set to 0 to exclude negative matches, as in the Jaccard coefficient); w_{ijk} can also be used to exclude similarity components when one or both values are missing for variable k .

Single Linkage Clustering

Once a proximity matrix has been defined, the next step is to form the clusters in a hierarchical sequence. There are many algorithms for doing this, depending on the way in which clusters are merged or divided. The algorithm usually entails defining proximity between clusters, as well as between individuals as outlined above. In one of the simplest hierarchical clustering methods, *single linkage* [14], also known as the *nearest neighbor technique*, the distance between clusters is defined as that between the closest pair of individuals, where only pairs consisting of one individual from each group are considered. Single linkage can be applied as an agglomerative method, or as a divisive method by initially splitting the data into two clusters with maximum nearest neighbor distance. The fusions made at each stage of agglomerative single linkage are now shown in a numerical example.

Consider the following distance matrix:

$$\mathbf{D}_1 = \begin{array}{ccccc} & 1 & 2 & 3 & 4 & 5 \\ \begin{array}{c} 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{array} & \begin{array}{c} 0.0 \\ 2.0 \\ 6.0 \\ 10.0 \\ 9.0 \end{array} & \begin{array}{c} \\ 0.0 \\ 5.0 \\ 9.0 \\ 8.0 \end{array} & \begin{array}{c} \\ \\ 0.0 \\ 4.0 \\ 5.0 \end{array} & \begin{array}{c} \\ \\ \\ 0.0 \\ 3.0 \end{array} & \begin{array}{c} \\ \\ \\ \\ 0.0 \end{array} \end{array} \quad (4)$$

The smallest entry in the matrix is that for individuals 1 and 2, consequently these are joined to form a two-member cluster. Distances between this cluster and the other three individuals are obtained as

$$\begin{aligned} d_{(1,2)3} &= \min[d_{13}, d_{23}] = d_{23} = 5.0 \\ d_{(1,2)4} &= \min[d_{14}, d_{24}] = d_{24} = 9.0 \\ d_{(1,2)5} &= \min[d_{15}, d_{25}] = d_{25} = 8.0 \end{aligned} \quad (5)$$

A new matrix may now be constructed whose entries are inter-individual and cluster-individual distances.

$$\mathbf{D}_2 = \begin{array}{ccccc} & (1, 2) & 3 & 4 & 5 \\ \begin{array}{c} (1, 2) \\ 3 \\ 4 \\ 5 \end{array} & \begin{array}{c} 0.0 \\ 5.0 \\ 9.0 \\ 8.0 \end{array} & \begin{array}{c} \\ 0.0 \\ 4.0 \\ 5.0 \end{array} & \begin{array}{c} \\ \\ 0.0 \\ 3.0 \end{array} & \begin{array}{c} \\ \\ \\ 0.0 \end{array} \end{array} \quad (6)$$

The smallest entry in $\mathbf{D}_2$ is that for individuals 4 and 5, so these now form a second two-member cluster and a new set of distances found:

$$\begin{aligned} d_{(1,2)3} &= 5.0 \text{ as before} \\ d_{(1,2)(4,5)} &= \min[d_{14}, d_{15}, d_{24}, d_{25}] = d_{25} = 8.0 \\ d_{(4,5)3} &= \min[d_{34}, d_{35}] = d_{34} = 4.0 \end{aligned} \quad (7)$$

These may be arranged in a matrix $\mathbf{D}_3$:

$$\mathbf{D}_3 = \begin{array}{ccccc} & (1, 2) & 3 & (4, 5) \\ \begin{array}{c} (1, 2) \\ 3 \\ (4, 5) \end{array} & \begin{array}{c} 0.0 \\ 5.0 \\ 8.0 \end{array} & \begin{array}{c} \\ 0.0 \\ 4.0 \end{array} & \begin{array}{c} \\ \\ 0.0 \end{array} \end{array} \quad (8)$$

The smallest entry is now $d_{(4,5)3}$ and individual 3 is added to the cluster containing individuals 4 and 5. Finally, the groups containing individuals 1,2 and 3,4,5 are combined into a single cluster.

Dendrogram

The process agglomerative process above is illustrated in a dendrogram in Figure 1. The *nodes* of

Figure 1 A dendrogram produced by single linkage hierarchical clustering. The process successively merges five individuals based on their pairwise distances (see text) to form a sequence of five partitions P1–P5

the dendrogram represent clusters and the lengths of the stems (*heights*) represent the dissimilarities at which clusters are joined. The same data and clustering procedure can give rise to 2^{n-1} dendrograms with different appearances, and it is usual for the software to choose an order for displaying the nodes that is optimal (in some sense). Drawing a line across the dendrogram at a particular height defines a particular partition or cluster solution (such that clusters below that height are distant from each other by at least that amount). The structure resembles an evolutionary tree and it is in applications where hierarchies are implicit in the subject matter, such as biology and anthropology, where hierarchical clustering is perhaps most relevant. In other areas it can still be used to provide a starting point for other methods, for example, optimization methods such as *k-means*.

While the dendrogram illustrates the hierarchical process by which series of cluster solutions are produced, low dimensional plots of the data (e.g., **principal component** plots) are more useful for interpreting particular solutions. Such plots can show the relationships among clusters, and among individual cases within clusters, which may not be obvious from a dendrogram. Comparisons between the mean levels or frequency distributions of individual variables within clusters, and the identification of representative members of the clusters (*centrotypes* or *exemplars* [19]) can also be useful. The latter are defined as the objects having the maximum within-cluster average similarity (or minimum dissimilarity), for example, the *medoid* (the object with the minimum absolute distance to the other members of the cluster).

The dendrogram can be regarded as representing the original relationships amongst the objects, as implied by their observed proximities. Its success in doing this can be measured using the *cophenetic matrix*, whose elements are the heights where two objects become members of the same cluster in the dendrogram. The product-moment correlation between the entries in the cophenetic matrix and the corresponding ones in the proximity matrix (excluding 1s on the diagonals) is known as the *cophenetic correlation*. Comparisons using the cophenetic correlation can also be made between different dendrograms representing different clusterings of the same data set. Dendrograms can be compared using randomization tests to assess the statistical significance of the cophenetic correlation [11].

Other Agglomerative Clustering Methods

Single linkage operates directly on a proximity matrix. Another type of clustering, *centroid clustering* [15], however, requires access to the original data. To illustrate this type of method, it will be applied to the set of bivariate data shown in Table 1.

Suppose Euclidean distance is chosen as the inter-object distance measure, giving the following distance matrix:

$$\mathbf{D}_1 = \begin{matrix} & \begin{matrix} 1 & 2 & 3 & 4 & 5 \end{matrix} \\ \begin{matrix} 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{matrix} & \begin{matrix} 0.0 \\ 1.0 & 0.0 \\ 5.39 & 5.10 & 0.0 \\ 7.07 & 7.0 & 2.24 & 0.0 \\ 7.07 & 7.28 & 3.61 & 2.0 & 0.0 \end{matrix} \end{matrix} \quad (9)$$

Examination of $\mathbf{D}_1$ shows that d_{12} is the smallest entry and objects 1 and 2 are fused to form a group. The mean vector (centroid) of the group is calculated (1,1.5) and a new Euclidean distance matrix is calculated.

$$\mathbf{D}_2 = \begin{matrix} & \begin{matrix} (1, 2) & 3 & 4 & 5 \end{matrix} \\ \begin{matrix} (1, 2) \\ 3 \\ 4 \\ 5 \end{matrix} & \begin{matrix} 0.0 \\ 5.22 & 0.0 \\ 7.02 & 2.24 & 0.0 \\ 7.16 & 3.61 & 2.0 & 0.0 \end{matrix} \end{matrix} \quad (10)$$

The smallest entry in $\mathbf{D}_2$ is d_{45} and objects 4 and 5 are therefore fused to form a second group, the mean vector of which is (8.0,1.0). A further distance matrix $\mathbf{D}_3$ is now calculated.

$$\mathbf{D}_3 = \begin{matrix} & \begin{matrix} (1, 2) & 3 & (4, 5) \end{matrix} \\ \begin{matrix} (1, 2) \\ 3 \\ (4, 5) \end{matrix} & \begin{matrix} 0.0 \\ 5.22 & 0.0 \\ 7.02 & 2.83 & 0.0 \end{matrix} \end{matrix} \quad (11)$$

In $\mathbf{D}_3$ the smallest entry is $d_{(45)3}$ and so objects 3,4, and 5 are merged into a three-member cluster. The final stage consists of the fusion of the two remaining groups into one.

Table 1 Data on five objects used in example of centroid clustering

Object	Variable 1	Variable 2
1	1.0	1.0
2	1.0	2.0
3	6.0	3.0
4	8.0	2.0
5	8.0	0.0

4 Hierarchical Clustering

Different definitions of intergroup proximity give rise to different agglomerative methods. *Median linkage* [5] is similar to centroid linkage except that the centroids of the clusters to be merged are weighted equally to produce the new centroid of the merged cluster, thus avoiding the more numerous of the pair of clusters dominating. The new centroid is intermediate between the two constituent clusters. In the centroid linkage shown above Euclidean distance was used, as is usual. While other proximity measures are possible with centroid or median linkage, they would lack interpretation in terms of the raw data. *Complete linkage* (or *furthest neighbor*) [16], is opposite to single linkage, in the sense that distance between groups is now defined as that of the most distant pair of individuals (the *diameter* of the cluster). In (*group*) *average linkage* [15], the distance between two clusters is the average of the distance between all pairs of individuals that are made up of one individual from each group. Average, centroid, and median linkage are also known as UPGMA, UPGMC, and WPGMC methods respectively (U: unweighted; W: weighted; PG: pair group; A: average; C: centroid).

Ward introduced a method based on minimising an objective function at each stage in the hierarchical process, the most widely used version of which is known as *Ward's method* [17]. The objective at each stage is to minimize the increase in the total within-cluster error sum of squares. This increase is in fact a function of the weighted Euclidean distance between the centroids of the merged clusters. Lance and William's *flexible* method is defined by values of the parameters of a general recurrence formula [10] and many of the standard methods mentioned above can be defined in terms of the parameters of the Lance and Williams formulation.

Divisive Clustering Methods

As mentioned earlier, divisive methods operate in the other direction from agglomerative methods, starting with one large cluster and successively splitting clusters. *Polythetic divisive* methods are relatively rarely used and are more akin to the agglomerative methods discussed above, since they use all variables simultaneously, and are computationally demanding. For data consisting of binary variables, however,

relatively simple and computationally efficient *monothetic divisive* methods are available. These methods divide clusters according to the presence or absence of each variable, so that at each stage clusters contain members with certain attributes that are either all present or all absent.

Instead of cluster homogeneity, the attribute used at each step in a divisive method can be chosen according to its overall association with other attributes: this is sometimes termed *association analysis* [18]. The split at each stage is made according to the presence or absence of the attribute whose association with the others (i.e., the summed criterion above) is a maximum. For example for one pair of variables V_i and V_j with values 0 and 1 the frequencies observed might be as follows:

	V_i	1	0
V_j			
	1	a	b
	0	c	d

Examples of measures of association based on these frequencies (summed over all pairs of variables) are $|ad - bc|$ and $(ad - bc)^2 n / [(a + b)(a + c)(b + d)(c + d)]$. Hubálek gives a review of 43 such coefficients [7]. A general problem with this method is that the possession of a particular attribute, which is either rare or rarely found in combination with others, may take an individual down the 'wrong' path.

Choice of Number of Clusters

It is often the case that an investigator is not interested in the complete hierarchy but only in one or two partitions obtained from it (or 'cluster solutions'), and this involves deciding on the number of groups present. In standard agglomerative or polythetic divisive clustering, partitions are achieved by selecting one of the solutions in the nested sequence of clusterings that comprise the hierarchy. This is equivalent to cutting a dendrogram at an optimal height (this choice sometimes being termed the *best cut*). The choice of height is generally based on large changes in fusion levels in the dendrogram, and a *scree-plot* of height against number of clusters can be used as an informal guide. A relatively widely used formal test procedure is based on the relative sizes of the different fusion levels [13], and a number of other formal approaches for determining

the number of clusters have been reviewed [12] (*see Number of Clusters*).

Choice of Cluster Method

Apart from the problem of deciding on the number of clusters, the choice of the appropriate method in

any given situation may also be difficult. Hierarchical clustering algorithms are only stepwise optimal, in the sense that at any stage the next step is chosen to be optimal in some sense but that may not guarantee the globally optimal partition, had all possibilities had been examined. Empirical and theoretical studies have rarely been conclusive. For example,

Figure 2 Dendrogram produced by cluster analysis of similarity judgments of pain descriptors obtained from healthy volunteers, using average-linkage cluster analysis. The data are healthy peoples' responses to the descriptors in the MAPS (Multidimensional Affect and Pain Survey). The dendrogram has been cut at 30 clusters and also shows 'superclusters' joining at higher distances. A separate factor analysis obtained from patients' responses of the 30-cluster concepts found six factors, indicated along the left-hand side

single linkage tends to have satisfactory mathematical properties and is also easy to program and apply to large data sets, but suffers from ‘chaining’, in which separated clusters with ‘noise’ points in between them tend to be joined together. Ward’s method often appears to work well but may impose a spherical structure where none exists and can be sensitive to outliers. Relatively recently, however, hierarchical methods based on the *classification likelihood* have been developed [1]. Such model-based methods are more flexible than the standard methods discussed above, in that they assume an underlying mixture of multivariate normal distributions and hence allow the detection of elliptical clusters, possibly with varying sizes and orientations. They also have the advantage of providing an associated test of the weight of evidence for varying numbers of clusters (*see Model Based Cluster Analysis; Finite Mixture Distributions*).

An Example of Clustering

As a practical example, Figure 2 shows the top part of a dendrogram resulting from clustering pain concepts [2]. The similarities between 101 words describing pain (from the Multidimensional Affect and Pain Survey) were directly assessed by a panel of health people using a *pile-sort* procedure, and these similarities were analyzed using average linkage clustering. Thirty pain concept clusters (e.g., ‘cutaneous sensations’) could be further grouped into ‘superclusters’ (e.g., ‘somatosensory pain’) and these clusters and superclusters are shown on the dendrogram. Individual pain descriptors that comprise the clusters are not shown (the dendrogram has been ‘cut’ at the 30-cluster level). The results of a factor analysis of responses by cancer outpatients is shown along the left-hand edge, and this was used to validate the structure of the MAPS pain concepts derived from the cluster analysis.

Further Information

General reviews of cluster analysis are available that include descriptions of hierarchical methods and their properties, and examples of their application [3,4], including one that focuses on robust methods [9]. Recently, specialist techniques have been developed for newly expanding subject areas such as genetics [8].

Hierarchical Item Response Theory Modeling

Item response data are frequently collected in settings where the objects of measurement are hierarchically nested (e.g., students within schools, clients within therapists, repeated measures within persons). Such data structures commonly lead to statistical dependence among observations. For example, test scores from students attending the same school are usually more similar than scores from students attending different schools. While this creates problems for statistical analyses that require independence, it also offers opportunities for understanding the nature of contextual influence [20], such as characteristics of effective schools. **Hierarchical models**, referred to elsewhere as *multilevel*, *random coefficients*, or *mixed effects* models, account for this dependence through the use of random effects (see **Linear Multilevel Models**).

For traditional users of hierarchical models, the synthesis of hierarchical models with item response theory (IRT) (see **Item Response Theory (IRT) Models for Polytomous Response Data & Intrinsic Linearity**) allows the practical advantages of the latent trait metric (see **Latent Variable**) in IRT to be realized in hierarchical settings where observed measures (e.g., test scores) can be problematic [17]. For traditional users of IRT, hierarchical extensions allow more complex IRT models that can account for the effects that higher level units (e.g., schools) have on lower level units (e.g., students) [9, 13]. Hierarchical IRT is often portrayed more generally than this, however, as even the simplest of IRT models can be viewed as hierarchical models where multiple item responses are nested within persons [2, 14]. From this perspective, hierarchical modeling offers a very broad framework within which virtually all IRT models and applications (e.g., differential item functioning; equating) can be unified and generalized, as necessary, to accommodate unique sources of dependence that may arise in different settings [1, 19]. In this entry, we consider two classes of hierarchical IRT models, one based on a nesting of item responses within persons, the other a nesting of item responses within both persons and items.

Hierarchical IRT Models with Random Person Effects

In one form of hierarchical IRT modeling, item responses (Level 1 units) are portrayed as nested within persons (Level 2 units) [2]. A Level-1 model, $P(U_{ij} = m | \theta_i, \xi_j)$, also called a *within-person model*, expresses the probability of item score m conditional upon person parameters, denoted θ_i (generally latent trait(s)), and item parameters, denoted ξ_j (e.g., item difficulty). Any of the common dichotomous or polytomous IRT models (see **Item Response Theory (IRT) Models for Polytomous Response Data**) (see [4] for examples) could be considered as within-person models.

At Level 2, variability in the person parameters is modeled through a *between-person* model. In hierarchical IRT, it is common to model the latent trait as a function of other person variables, such as socioeconomic status or gender. For example, a between-person model might be expressed as:

$$\theta_i = \beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \cdots + \beta_p X_{ip} + \tau_i \quad (1)$$

where $X_{i1}, X_{i2}, \dots, X_{ip}$ denote p person variables, β_0 is an intercept parameter, $\beta_1, \dots, \beta_p$ are regression coefficient parameters, and τ_i a residual, commonly assumed to be normally distributed with mean 0 and variance τ_r . It is the presence of this residual that makes the person effect a random effect. The item parameters of the IRT model, usually assumed constant across persons, represent fixed effects.

The combination of a within-person model and a between-person model as described above provides a multilevel representation of Zwinderman's [25] manifest predictors model. Other existing IRT models can also be viewed as special cases. For example, a multigroup IRT model [3] uses group identifier variables as predictors in the between-person model. Traditional IRT models (e.g., Rasch, two-parameter models) have no predictors.

There are several advantages of portraying IRT models within a hierarchical framework [10, 13]. First, it allows covariates of the person traits to be used as collateral information for IRT estimation. This can lead to improved estimation of not only the person traits, but also (indirectly) the item parameters [11, 12]. (However, the latter effects tend to be quite small in most practical applications [2].)

A second advantage is improved estimation of relationships between person variables and the latent

2 Hierarchical Item Response Theory Modeling

traits. A hierarchical IRT model avoids problems of attenuation bias that are introduced when using a two-step estimation procedure, specifically, one that first estimates the person traits using an IRT model, and then in a separate analysis regresses the trait estimates on the person variables. When these analyses are executed simultaneously, as in hierarchical IRT, the regression coefficient estimates are based on the latent traits and thus are not attenuated due to estimation error.

A third advantage of hierarchical IRT is its capacity to include additional levels above persons [9, 13]. To illustrate, we consider a three-level dataset from the 1999 administration of the mathematics section of the Texas Assessment of Academic Skills (TAAS). The dataset contains correct/incorrect item responses to 52 items for a sample of 26,289 fifth-graders from 363 schools. Student variables related to socioeconomic status (FLUNCH=1 implies free or reduced-price lunch, 0=regular-price lunch) and gender (GENDER=1 implies female, 0=male) were also considered. Here we analyze just 20 of the 52 items. The three-level model involves item responses nested with students, and students nested within schools.

For the within-person model, we use a **Rasch model**. In a Rasch model, the probability of correct item response is modeled through an item difficulty parameter b_j and a single person trait parameter θ_{ik} , the latter now double-indexed to identify student i from school k :

$$P(U_{ik,j} = 1 | \theta_{ik}, b_j) = \frac{\exp(\theta_{ik} - b_j)}{1 + \exp(\theta_{ik} - b_j)}. \quad (2)$$

At Level 2, between-student variability is modeled as:

$$\theta_{ik} = \beta_{0k} + \beta_{1k}\text{FLUNCH}_{ik} + \beta_{2k}\text{GENDER}_{ik} + r_{ik}, \quad (3)$$

where β_{0k} , β_{1k} , and β_{2k} are the intercept and regression coefficient parameters for school k ; r_{ik} is a normally distributed residual with mean zero and variance τ_r .

Next, we add a third level associated with school. At the school level, we can account for the possibility that certain effects at the student level (represented by the coefficients β_{0k} , β_{1k} , β_{2k}) may vary across schools. In the current model, we allow for between-school variability in the intercepts

(β_{0k}) and the within-school FLUNCH effects (β_{1k}). We also create a school variable, FLUNCH.SCH $_k$, the mean of FLUNCH across all students within school k , to represent the average socioeconomic status of students within the school. The variable FLUNCH.SCH $_k$ is added as a predictor both of the school intercepts and the within-school FLUNCH effect. This results in the following Level-3 (between-school) model:

$$\beta_{0k} = \gamma_{00} + \gamma_{01}\text{FLUNCH.SCH}_k + u_{0k}, \quad (4)$$

$$\beta_{1k} = \gamma_{10} + \gamma_{11}\text{FLUNCH.SCH}_k + u_{1k}, \quad (5)$$

$$\beta_{2k} = \gamma_{20}. \quad (6)$$

In this representation, each of the γ parameters represents a fixed effect, while the u_{0k} and u_{1k} are random effects associated with the school intercepts and school FLUNCH effects, respectively. Across schools, we assume (u_{0k}, u_{1k}) to be bivariate normally distributed with mean (0,0) and covariance matrix $\mathbf{T}_u$, having diagonal elements $\tau_{u_{00}}$ and $\tau_{u_{11}}$. (Note that by omitting a similar residual for β_{2k} , the effects of GENDER are assumed to be the same, that is, fixed, across schools.) Variations on the above model could be considered by modifying the nature of effects (fixed versus random) and/or predictors of the effects.

To estimate the model above, we follow a procedure described by Kamata [9]. In Kamata's method, a hierarchical IRT model is portrayed as a hierarchical **generalized linear model**. Random person effects are introduced through a random intercept, while item effects are introduced through the fixed (across persons) coefficients of item-identifier dummy variables at Level 1 of the model (see [9] for details). In this way, the model can be estimated using a quasi-likelihood algorithm implemented for generalized linear models in the software program HLM [16].

A portion of the results is shown in Tables 1 and 2. In Table 1, the fixed effect estimates are seen to be statistically significant for FLUNCH, FLUNCH.SCH, and GENDER, implying lower levels of math ability on average for students receiving free or reduced-price lunch within a school ($\hat{\gamma}_{10} = -.53$), and also lower (on average) abilities for students coming from schools that have a larger percentage of students that receive free or reduced-price lunch ($\hat{\gamma}_{01} = -.39$). The effect for gender is significant but weak ($\hat{\gamma}_{20} = .04$), with females having slightly higher ability. No

Table 1 Estimates of fixed and random effect parameters in multilevel Rasch model, Texas assessment of academic skills data

Fixed effect estimates	Coeff	se	t-stat	Approx. df	P value

γ_{01} , FLUNCH.SCH	-.39	.06	-6.15	361	.000
γ_{10} , FLUNCH	-.53	.04	-12.04	361	.000
γ_{11} , FLUNCH $\times$ FLUNCH.SCH	.05	.08	.67	361	.503
γ_{20} , GENDER	.04	.01	3.02	26824	.003
Variance estimates	Variance	χ^2	df	P value	Reliability
τ_r	1.26	48144	23445	.000	.927
$\tau_{u_{00}}$	.16	2667	227	.000	.888
$\tau_{u_{11}}$	.05	383	227	.000	.345

significant interaction was detected for FLUNCH and FLUNCH.SCH.

The variance estimates, also shown in Table 1, suggest significant between-school variability both in the residual intercepts ($\hat{\tau}_{u_{00}} = .16$) and in the residual FLUNCH effects ($\hat{\tau}_{u_{11}} = .05$). This implies that even after accounting for the effects of FLUNCH.SCH, there remains significant between-school variability in both the mean ability levels of non-FLUNCH students, and in the within-school effects of FLUNCH. Likewise, significant between-student variability remains across students within school ($\tau_r = 1.26$) even after accounting for the effects of FLUNCH and GENDER. Recall that Rasch item difficulties are also estimated as fixed effects in the model. These estimates (not shown here) ranged from -2.49 to 2.06.

Table 2 provides empirical Bayes estimates of the residuals for three schools (see **Random Effects in Multivariate Linear Models: Prediction**). Such estimates allow a school-specific inspection of the two effects allowed to vary across schools (in this model, the intercept, u_{0k} , and FLUNCH, u_{1k} , effects). More specifically, they indicate how each school's effect departs from what is expected given

the corresponding fixed effects (in this model, the fixed intercept and FLUNCH.SCH effects). These estimates illustrate another way in which hierarchical IRT can be useful, namely, its capacity to provide group-level assessment. Recalling that both residuals have means of zero across schools, we observe that School 1 has a lower intercept (-1.03), implying lower ability levels for non-FLUNCH students, and a more negative FLUNCH effect (-0.26), than would be expected given the school's level on FLUNCH.SCH (.30). School 2, which has a much higher proportion of FLUNCH students than School 1 (.93), has a higher than expected intercept and a more negative than expected FLUNCH effect, while School 3, with FLUNCH.SCH=.17, has a higher than expected intercept, but an FLUNCH effect that is equivalent to what is expected.

Despite the popularity of Kamata's method, it is limited to use with the Rasch model. Other estimation methods have been proposed for more general models. For example, other models within the Rasch family (e.g., Master's partial credit model), can be estimated using a general EM algorithm in the software CONQUEST [24]. Still more general models, such as hierarchical two parameter IRT models, can

Table 2 Examples of empirical Bayes estimates for individual schools, Texas assessment of academic skills data

School	N	Empirical Bayes estimates				FLUNCH.SCH	Fixed effects	
		$\hat{u}_0$	se	$\hat{u}_1$	se		$\hat{\gamma}_{00} + \hat{\gamma}_{01}\text{FLUNCH.SCH}$	$\hat{\gamma}_{10} + \hat{\gamma}_{11}\text{FLUNCH.SCH}$

N = number of students; FLUNCH.SCH = proportion of students receiving free or reduced-price lunch.

be estimated using fully Bayesian methods, such as Gibbs' sampling [6, 7]. Such procedures are appealing in that they provide a full characterization of the joint posterior distribution of model parameters, as opposed to point estimates. Because they are easy to implement, they also permit greater flexibility in manipulation of other features of the hierarchical IRT model. For example, Maier [10] explores use of alternative distributions for the residuals (e.g., inverse chi-square, uniform) in a hierarchical Rasch model.

Several advantages of hierarchical IRT modeling can be attributed to its use of a latent trait. First, the use of a **latent variable** as the outcome in the between-person model allows for more realistic treatment of measurement error. When modeling test scores as outcomes, for example, variability in the standard error of measurement across persons is not easily accounted for, as a common residual variance applies for all persons. Second, the invariance properties of IRT allow it to accommodate a broader array of data designs, such as matrix sampled educational assessments (as in the National Assessment of Educational Progress), or others that may involve missing data. Finally, the interval level properties of the IRT metric can be beneficial. For example, Raudenbush, Samson, and Johnson [16] note the value of a Rasch trait metric when modeling self-reported criminal behavior across neighborhoods, where simple counts of crime tend to produce observed scores that are highly skewed and lack interval scale properties.

Hierarchical IRT Models with Both Random Person and Item Effects

Less common, but equally useful, are hierarchical IRT models that model random item effects. Such models typically introduce a between-item model in which the item parameters of the IRT model become outcomes. Modeling the predictive effects of item features on item parameters can be very useful. Advantages include improved estimation of the item parameters (i.e., collateral information), as well as information about item features that can be useful for item construction and item-level validity checks [4]. A common IRT model used for this purpose is Fischer's [5] linear logistic test model [LLTM]. In the LLTM, Rasch item difficulty is expressed as a weighted linear combination of

prespecified item characteristics, such as the cognitive skill requirements of the item. Hierarchical IRT models can extend models such as the LLTM by allowing item parameters to be random, thus allowing for less-than-perfect prediction of the item difficulty parameters [8].

A hierarchical IRT model with random person and item effects can be viewed as possessing two forms of nesting, as item responses are nested within both persons and items. Van den Noortgate, De Boeck, and Meulders [21] show how random item effect models can be portrayed as *cross-classified hierarchical models* [20] in that each item response is associated with both a person and item. With cross-classified models, it is possible to consider not only main effects associated with item and person variables, but also item-by-person variables [19, 21]. This further extends the range of applications that can be portrayed within the hierarchical IRT framework. For example, hierarchical IRT models such as the random weights LLTM [18], where the LLTM weights vary randomly across persons, and dynamic Rasch models [22], where persons learn over the course of a test [22], can both be portrayed in terms of item-by-person covariates [19]. Similarly, IRT applications such as differential item functioning can be portrayed in a hierarchical IRT model where the product of person group by item is a covariate [19].

Additional levels of nesting can also be defined for the items. For example, in the hierarchical IRT model of Janssen, Tuerlinckx, Meulders, and De Boeck [8], items are nested within target content categories. An advantage of this model is that a prototypical item for each category can be defined, thus allowing criterion-related classification decisions based on each person's estimated trait level.

Different estimation strategies have been considered for random person and item effect models. Using the cross-classified hierarchical model representation, Van den Noortgate et al. [21] propose use of quasi-likelihood procedures implemented in the SAS-macro GLIMMIX [23]. Patz and Junker [14] presented a very general Markov chain Monte Carlo strategy for hierarchical IRT models that can incorporate both item and person covariates. A related application is given in Patz, Junker, Johnson, and Moriano [15], where dependence due to rater effects is addressed. General formulations such as this offer the clearest indication of the future potential for hierarchical IRT

models, which should continue to offer the methodologist exciting new ways of investigating sources of hierarchical structure in item response data.

Hierarchical Models

Many types of data in the behavioral sciences are inherently nested or hierarchical [15]. For example, students are nested within classes that are nested within schools. Different cells are nested within different regions of the brain. A consequence of this nesting is that within-unit observations are unlikely to be independent; to some extent, within-unit observations (e.g., students within classes) are correlated or more similar to each other than between-unit observations (e.g., students from different classes). The statistical consequences of nonindependence can be severe [7], and the assumptions of traditional statistical models, such as the **generalized linear model** (GLM), become violated. This in turn may influence the size of the standard errors and, hence, statistical significance tests.

Hierarchical linear models (HLM; sometimes referred to as random coefficient, mixed-effects, or

multilevel models, *see* **Generalized Linear Mixed Models** and **Linear Multilevel Models**) represent a class of models useful for testing substantive questions when the data are inherently nested or when nonindependence of observations is a concern. This chapter is designed to be a simple introduction to the HLM. Readers should consult these excellent sources for technical details [1, 2, 4–6, 8, 10, 14].

A Simple Introduction to the HLM

Figure 1 visually shows the typical GLM model (here, a regression-based model) and contrasts it to the HLM. Below each figure is the statistical model ((1) for the GLM and (2–4) for the HLM). To illustrate this difference further, consider the following example. Suppose we want to understand how job autonomy relates to job satisfaction. We know they are likely to be positively related and so we may model the data using simple regression. However, what if we suspect supervisory style

Figure 1 Comparison of GLM to HLM

2 Hierarchical Models

Figure 2 Illustration of what random effects for intercepts and slopes really mean

(e.g., autocratic, democratic) also influences satisfaction? Note employees are nested within supervisors – a given supervisor may be in charge of numerous employees, and, therefore, employees who have a particular supervisor may share some similarities not shared by employees of another supervisor. This makes it necessary to use HLM. Supervisors may have independent and direct effects on satisfaction (arrow 2), or moderate the relationship between autonomy and satisfaction (arrow 1).

Equation (1) is the classic regression model, which assumes errors are independent and normally distributed with a mean of zero and constant variance (see **Multiple Linear Regression**). The model assumes that the regression weights are constant across different supervisors; hence, there are no subscripts for B_0 and B_1 . This exemplifies a *fixed effects model* because the weights do not vary across units (see **Fixed and Random Effects**). In contrast, the HLM exemplifies a *random effects model* because the regression weights B_0 and B_1 vary across supervisors (levels of j ; see (2)) who are assumed to be randomly selected from a population of supervisors (see **Fixed and Random Effects**). Figure 2 illustrates this visually, where hypothetical regression lines are

shown for 10 subjects. The solid lines represent five subjects from one unit, the dashed lines represent five subjects from a different unit. Notice that across both units there is considerable variability in intercepts and slopes, with members of the second unit tending to show negative slopes (denoted by dashed lines). The solid bold line represents the regression line obtained from a traditional regression – clearly an inappropriate representation of this data.

The real benefit of HLM comes in two forms. First, because it explicitly models the nonindependence/heterogeneity in the data, it provides accurate standard errors and, hence, statistical significance tests. Second, it allows one to explain between-unit differences in the regression weights. This can be seen in (3) and (4). Equations (3) and (4) states between-unit differences in the intercept (slope) are explained by supervisory style. Note that in this model, the supervisory effect is a fixed effect.

Level 2 predictors may either be categorical (e.g., experimental condition) or continuous (e.g., individual differences). It is important to center the continuous data to facilitate interpretation of the lower level effects (see **Centering in Linear Multilevel Models**). Often, the most useful centering

method is to center the Level 2 predictors across all units (grand mean centering), and then center the Level 1 predictors within each unit (unit mean centering).

The basic HLM assumptions are (a) errors at both levels have a mean of zero, (b) Level 1 and Level 2 errors are uncorrelated with each other, (c) Level 1 errors (e_{ij}) have a constant variance (sigma-squared), and (d) Level 2 errors take a known form, but this form allows heterogeneity (nonconstant variance), and covariances among the error terms. Note also that HLM models frequently use restricted maximum likelihood (REML) estimation that assumes multivariate normality (*see Maximum Likelihood Estimation; Catalogue of Probability Density Functions*).

Comparing and Interpreting HLM Models

The HLM provides several estimates of model fit. These frequently include the -2 Residual Log Likelihood, **Akaike's Information Criterion** (AIC), and

the Bayesian Information Criterion (BIC). Smaller values for AIC and BIC are better. There are no statistical significance tests associated with these indices, so one must conduct a model comparison approach in which simple models are compared to more complicated models. The difference between the simple and complex models is evaluated via the change in -2 Residual Log Likelihood (distributed as a chi-square), and/or examining which has the smaller AIC and BIC values. Table 1 shows a generic sequence of model comparisons for HLM models. The model comparison approach permits only the minimum amount of model complexity to explain the data.

HLM also provides statistical significance tests of fixed and random effects. Statistical significance tests for the fixed effects are interpreted just like in the usual ordinary least squares (OLS) regression model. However, the statistical significance tests for the random effects should be avoided because they are often erroneous (see [13]). It is better

Table 1 Generic model comparison sequence for HLM

Step	Proc mixed command language
1. Determine the amount of nonindependence (nesting) in the dependent variable via the Intraclass Correlation Coefficient (ICC).	PROC MIXED COVTEST UPDATE; CLASS unit; MODEL dv = /SOLUTION CL DDFM = BW; RANDOM INTERCEPT / TYPE = UN SUB = unit; RUN;
2. Add the Level 1 fixed effects. Interpret the statistical significance values for these effects.	PROC MIXED COVTEST UPDATE; CLASS UNIT; MODEL dv = iv /SOLUTION CL DDFM = BW; RUN;
3. Allow the intercept to be a random effect. Compare the difference between this model to the previous model via the change in loglikelihoods, AIC, and BIC.	PROC MIXED COVTEST UPDATE; CLASS unit; MODEL dv = iv /SOLUTION CL DDFM = BW; RANDOM INTERCEPT / TYPE = UN SUB = unit; RUN;
4. One at a time, allow the relevant Level 1 predictor variables to become random effects. Compare the differences between models via the change in loglikelihoods, AIC, and BIC.	PROC MIXED COVTEST UPDATE; CLASS unit; MODEL dv = iv /SOLUTION CL DDFM = BW; RANDOM INTERCEPT iv / TYPE = UN SUB = unit; RUN;
5. Attempt to explain the random effects via Level 2 predictors. Interpret the statistical significance values for these effects.	PROC MIXED COVTEST UPDATE; CLASS unit; MODEL dv = iv lev2iv /SOLUTION CL DDFM = BW; RANDOM INTERCEPT iv / TYPE = UN SUB = unit; RUN;

Note: Capitalized SAS code refers to SAS commands and options; noncapitalized words are variables. *iv* refers to the Level 1 predictor and *lev2iv* refers to the Level 2 predictor.

to test the random effects using the model comparison approach described above and in Table 1 (see [3, 11]).

Example

Let us now illustrate how to model hierarchical data in SAS. Suppose we have 1567 employees nested within 168 supervisors. We hypothesize a simple two-level model identical to that shown in the lower part of Figure 1.

Following the model testing sequence in Table 1, we start with determining how much variance in satisfaction is explainable by differences between supervisors. This is known as an intraclass correlation coefficient (ICC) and is calculated by taking the variance in the intercept and dividing it by the sum of the intercept variance plus residual variance. Generic SAS notation for running all models is shown in Table 1. The COVTEST option requests significance tests of the random effects (although we know not to put too much faith in these tests), and the UPDATE option asks the program to keep us informed of the REML iteration progress. The CLASS statement identifies the Level 2 variable within which the Level 1 variables are nested (here referred to as ‘unit’). The statement `dv = /SOLUTION CL DDFM = BW` specifies the nature of the fixed effects (‘satisfy’ is the dependent variable; SOLUTION asks for significance tests for the fixed effects, CL requests confidence intervals, and DDFM = BW requests denominator degrees of freedom be calculated using the between-within method, see [9, 13]). The RANDOM statement is where we specify the random effects. Because the INTERCEPT is specified, we allow random variation among the intercept term. TYPE = UN specifies the structure of the random effects, where UN means unstructured (other options include variance components, etc.). SUB = unit again identifies the nesting variable. Because no predictor variable is specified in this model, it is equivalent to a one-way random effects Analysis of Variance (ANOVA) with ‘unit’ as the grouping factor. When we run this analysis, we find a variance component of 0.71 and residual variance of 2.78; therefore the $ICC = 0.71 / (0.71 + 2.78) = 0.20$. This means 20% of the variance in satisfaction can be explained by higher-level effects.

Step 2 includes autonomy and the intercept as fixed effects. This model is identical to the usual

regression model. Table 2 shows the command syntax and results for this model. The regression weights for the intercept (6.28) and autonomy (0.41) are statistically significant.

Step 3 determines whether there are between-unit differences in the intercept, which would represent a random effect. We start with the intercept and compare the fit indices for this model to those from the fixed-effects model. To conserve space, I note only that these comparisons supported the inclusion of the random effect for the intercept. The fourth step is to examine the regression weight for autonomy (also a random effect), and compare the fit of this model to the previous random intercept model. When we compare the two models, we find no improvement in model fit by allowing the slope parameter to be a random effect. This suggests the relationship between autonomy and satisfaction does not differ across supervisors. However, the intercept parameter does show significant variability (0.73) across units.

The last step is to determine whether supervisory style differences explain the variability in job satisfaction. To answer this question, we could include a measure of supervisory style as a Level 2 fixed effects predictor. Table 2 shows supervisory style has a significant effect (0.39).

Thus, one concludes (a) autonomy is positively related to satisfaction, and (b) this relationship is not moderated by supervisory style, but (c) there are between-supervisor differences in job satisfaction, and (d) supervisory style helps explain these differences.

Conclusion

Many substantive questions in the behavioral sciences must deal with nested and hierarchical data. Hierarchical models were developed to address these problems. This entry provided a brief introduction to such models and illustrated their application using SAS. But there are many extensions to this basic model. HLM can also be used to model longitudinal data and growth curves. In such models, the Level 1 model represents intraindividual change and the Level 2 model represents individual differences in intraindividual change (for introductions, see [3, 12]). HLM has many research and real-world applications and provides researchers with a powerful theory testing and building methodology.

High-dimensional Regression

In regression analysis, there are n observations y_i on a dependent variable (also known as outcome or criterion) that are related to n corresponding observations x_i on p independent variables (also known as inputs or predictors). Fitting regression models of some form or another is by far the most common uses of statistics in the sciences (*see Multiple Linear Regression*).

Statistical theory tells us to assume that the observed outcomes y_i are realizations of n random variables $\underline{y}_i$. We model the conditional expectation of $\underline{y}_i$ given x_i , or, to put it differently, we model the expected value of $\underline{y}_i$ as a function of x_i

$$\mathbf{E}(\underline{y}_i | x_i) = F(x_i), \quad (1)$$

where the function F must be estimated from the data. Often the function F is known except for a small number of parameters. This defines parametric regression. Sometimes F is unknown, except for the fact that we know that has a certain degree of continuity or smoothness. This defines **nonparametric regression**.

In this entry, we are specifically concerned with the situation in which the number of predictors is large. Through the years, the meaning of ‘large’ has changed. In the early 1900s, three was a large number, in the 1980s 100 was large, and at the moment we sometimes have to deal with situations in which there are 10 000 predictors. This means, in the regression context, that we have to estimate a function F of 10 000 variables. Modern data collection techniques in, for example, genetics, environmental monitoring, and consumer research lead to these huge datasets, and it is becoming clear that classical statistical techniques are useless for such data. Entirely different methods, sometimes discussed under the labels of ‘data mining’ or ‘machine learning’, are needed [5] (*see Data Mining*).

Until recently **multiple linear regression**, in which F is linear, was the only practical alternative to deal with a large number of predictors. Thus, we specialize our model to

$$\mathbf{E}(\underline{y}_i | x_i) = \sum_{s=1}^p \beta_s x_{is}. \quad (2)$$

It became clear rather soon that linear regression with a large number of predictors has many problems. The main ones are multicollinearity, often even singularity, and the resulting numerical instability of the estimated regression coefficients (*see Collinearity*).

An early attempt to improve this situation is using variable selection. We fit the model

$$\mathbf{E}(\underline{y}_i | x_i) = \sum_{s=1}^p \beta_s \delta_s x_{is}. \quad (3)$$

where δ_s is either zero or one. In fitting this model, we select a subset of the variables and then do a linear regression. Although variable selection methods appeared relatively early in the standard statistical packages, and became quite popular, they have the major handicap that they must solve the combinatorial problem of finding the optimum selection from among the 2^p possible ones. Since this rapidly becomes unsolvable in any reasonable amount of time, various heuristics have been devised. Because of the instability of high-dimensional linear regression problems, the various heuristics often lead to very different solutions. Two ways out of the dilemma, which both stay quite close to linear regression, have been proposed around 1980. The first is principal component regression (*see Principal Component Analysis*) or PCR, in which we have

$$\mathbf{E}(\underline{y}_i | x_i) = \sum_{t=1}^q \beta_t \left[\sum_{s=1}^p \alpha_{ts} x_{is} \right]. \quad (4)$$

Here we replace the p predictors by $q < p$ principal components and then perform the linear regression. This tackles the multicollinearity problem directly, but it inherits some of the problems of principal component analysis. How many components do we keep? And how do we scale our variables for the component analysis?

The second, somewhat more radical, solution is to use the **generalized additive model** or GAM discussed by [6]. This means

$$\mathbf{E}(\underline{y}_i | x_i) = \sum_{s=1}^p \beta_s \phi_s(x_{is}), \quad (5)$$

where we optimize the regression fit over both θ and the functions (transformations) ϕ . Usually we require $\phi \in \Phi$ where Φ is some finite dimensional subspace of functions, such as polynomials or splines with a

2 High-dimensional Regression

given knot sequence. Best fits for such models are easily computed these days by using alternating least squares algorithms that iteratively alternate fitting θ for fixed ϕ and fitting ϕ for fixed θ [1]. Although generalized additive models add a great deal of flexibility to the regression situation, they do not directly deal with the instability and multicollinearity that comes from the very large number of predictors. They do not address the data reduction problem, they just add more parameters to obtain a better fit.

A next step is to combine the ideas of PCR and GAM into projection pursuit regression or PPR [4]. The model now is

$$\mathbf{E}(\underline{y}_i | x_i) = \sum_{t=1}^q \phi_t \left[\sum_{s=1}^p \alpha_{ts} x_{is} \right]. \quad (6)$$

This is very much like GAM, but the transformations are applied to a presumably small number of linear combinations of the original variables. PPR regression models are closely related to neural networks, in which the linear combinations are the single hidden layer and the nonlinear transformations are sigmoids or other squashers (see **Neural Networks**). PPR models can be fit by general neural network algorithms.

PPR regression is generalized in Li's **slicing inverse regression** or SIR [7, 8], in which the model is

$$\mathbf{E}(\underline{y}_i | x_i) = F \left[\sum_{s=1}^p \alpha_{1s} x_{is}, \dots, \sum_{s=1}^p \alpha_{qs} x_{is} \right]. \quad (7)$$

For details on the SIR and PHD algorithms, we refer to (see **Slicing Inverse Regression**).

Another common, and very general approach, is to use a finite basis of functions h_{st} , with $t = 1, \dots, q_s$, for each of the predictors x_s . The basis functions can be polynomials, piecewise polynomials, or splines, or radical basis functions. We then approximate the multivariate function F by a sum of products of these basis functions. Thus we obtain the model

$$\mathbf{E}(\underline{y}_i | x_i) = \sum_{t_1=1}^{q_1} \dots \sum_{t_p=1}^{q_p} \theta_{t_1 \dots t_p} \times h_{1t_1}(x_{i1}) \times \dots \times h_{pt_p}(x_{ip}) \quad (8)$$

This approach is used in multivariate adaptive regression splines, or MARS, by [3]. The basis functions are splines, and they adapt to the data by locating the knots of the splines.

A different strategy is to use the fact that any multivariate function can be approximated by a multivariate step function. This fits into the product model, if we realize that multivariate functions constant on rectangles are products of univariate functions constant on intervals. In general, we fit

$$\mathbf{E}(\underline{y}_i | x_i) = \sum_{t=1}^q \theta_t I(x_i \in R_t). \quad (9)$$

Here, the R_t define a partitioning of the p -dimensional space of predictors, and the $I()$ are indicator functions of the q regions. In each of the regions the regression function is a constant. The problem, of course, is how to define the regions. The most popular solution is to use a recursive partitioning algorithm such as **Classification and Regression Trees**, or by the algorithm CART [2], which defines the regions as rectangles in variable space. Partitionings are refined by splitting along a variable, and by finding the variable and the split which minimize the residual sum of squares. If the variable is categorical, we split into two arbitrary subsets of categories. If the variable is quantitative, we split an interval into two pieces. This recursive partitioning builds up a binary tree, in which leaves are refined in each stage by splitting the rectangles into two parts.

It is difficult, at the moment, to suggest a best technique for high-dimensional regression. Formal statistical **sensitivity analysis**, in the form of standard errors and confidence intervals, is largely missing. Decision procedures, in the form of tests, are also in their infancy. The emphasis is on exploration and on computation. Since the data sets are often enormous, we do not really have to worry too much about significance, we just have to worry about predictive performance and about finding (mining) interesting aspects of the data.

Hill's Criteria of Causation

The term *criteria of causation* (often called *causal criteria*), applied to Sir Austin Bradford Hill's widely cited list [8] of factors to consider before inferring causation from an observed association, is something of a misnomer. Hill (1897–1991) [4, 13] never called these considerations *criteria* but rather referred to them as *viewpoints*, and he did not believe it useful to elaborate 'hard-and-fast rules of evidence' [8, p. 299] for causation. Nevertheless, the publication of Hill's landmark address to the Royal Society of Medicine [8] is frequently cited as the authoritative source for causal criteria in epidemiologic practice [23, 24].

Hill singled out nine factors to consider 'before we cry causation' [8, p. 299] when observing a statistical association: strength; consistency; specificity; temporality; biological gradient; plausibility; coherence; experiment; analogy (in the order originally presented). Hill was neither the first nor the last to propose such a list [21, 23]. It is curious that causal criteria are so closely associated with Hill's name, particularly given that many authors who apply what they call 'Bradford Hill criteria' select idiosyncratically from his list those items they prefer, producing subsets that often more closely resemble shorter lists proposed by others [23, 24]. The attribution to Hill perhaps reflects his professional stature due to his contributions to medical statistics and epidemiologic study design in the early twentieth century [1–5, 19, 22], although his eloquence has also been proposed as an explanation [7].

Implicit in Hill's articulation of how to decide whether an association is causal is the recognition, dating back to Hume [14], of a fundamental limitation of empirical sciences: cause–effect relations cannot be observed directly or proven true by logic and therefore must be inferred by inductive reasoning [17, 21]. Hill recognized that statistical association does not equate with causation and that all scientific findings are tentative and subject to being upset by advancing knowledge. At the same time, he warned passionately that this limitation of science 'does not confer upon us a freedom to ignore the knowledge that we already have, or to postpone the action it appears to demand at a given

time' [8, p. 300]. These words reveal Hill's conviction that scientific judgments about causation are required so that the knowledge can be used to improve human lives. It is clearly for this purpose that Hill offered his perspective on how to decide whether an association observed in data is one of cause and effect.

Hill's presentation on inferring causation, though replete with insight, did not constitute a complete thesis on causal inference. Hill did not explicitly define what he meant by each of the viewpoints, relying instead on illustrative examples. While qualifying his approach by stating 'none of my nine viewpoints can bring indisputable evidence for or against the cause-and-effect hypothesis' [8, p. 299], he offered no means of deciding whether these aspects hold when considering a given association, no hierarchy of importance among them, and no method for assessing them to arrive at an inference of causation. Hill included the list of nine viewpoints in four editions of his textbook of medical statistics from 1971 through 1991 [9–12], without further elaboration than appeared in the original paper.

History of Causal Criteria in Epidemiology

Discussions of causal criteria arose from the recognized limitations of the Henle-Koch postulates, formalized in the late nineteenth century to establish causation for infectious agents [6]. These postulates require the causal factor to be necessary and specific, apply only to a subset of infectious agents, and conflict with multifactorial causal explanations. The nonspecificity of causal agents was a particular concern [18]. Two lists of causal criteria published before 1960 did not include specificity (instead including consistency or replication, strength, dose-response, experimentation, temporality, and biological reasonableness) [23]. In 1964, the year before Hill's presentation, the Surgeon General's Committee on Smoking and Health elected to use explicit criteria to determine whether smoking caused the diseases under review; their list included consistency, strength, specificity, temporality, and biological coherence (under which they included biological mechanism, dose-response, and exclusion of alternate explanations such as bias) [23]. According to Hamill, one of the committee members, the committee did not consider the list 'hewn in stone or

intended for all time and all occasions, but as a formal description of how *we* drew our... conclusions... [7, p. 527]. Since the 1970s [20], Susser has advocated the use of causal criteria for discriminating between a true causal factor and 'an imposter' [21, pp. 637–8], proposing a refined list of criteria in 1991, including strength, specificity, consistency (both replicability and survivability on diverse tests of the causal hypothesis), predictive performance, and coherence (including theoretical, factual, biological, and statistical) [21]. Susser's historical analysis argues against ossified causal criteria ('epidemiologists have modified their causal concepts as the nature of their tasks has changed... Indeed, the current set of criteria may well be displaced as the tasks of the discipline change, which they are bound to do.' [21, pp. 646–7]).

Limitations of Criteria for Inferring Causation

With the exception of temporality, no item on any proposed list is necessary for causation, and none is sufficient. More importantly, it is not clear how to quantify the degree to which each criterion is met, let alone how to aggregate such results into a judgment about causation. In their advanced epidemiology textbook, Rothman and Greenland question the utility of each item on Hill's list except temporality [17]. Studies of how epidemiologists apply causal criteria reveal wide variations in how the criteria are selected, defined, and judged [24]. Furthermore, there appear to be no empirical assessments to date of the validity or usefulness of causal criteria (e.g., retrospective studies of whether appealing to criteria improves the conclusions of an analysis). In short, the value of checklists of criteria for causal inference is severely limited and has not been tested.

Beyond Causal Criteria

Although modern thinking reveals limitations of causal criteria, Hill's landmark paper contains crucial insights. Hill anticipated modern statistical approaches to critically analyzing associations, asking 'Is there any way of explaining the set of facts before us, is there any other answer equally, or more, likely than cause and effect?' [8, p. 299]. Ironically, although Hill correctly identified this as the fundamental question, consulting a set of criteria does

little to answer this question. Recent developments in methods for uncertainty quantification [15], however, are creating tools for assessing the probability that an observed association is due to alternative explanations, which include random error or study bias rather than a causal relationship. Equally important, Hill, though described as the greatest medical statistician of the twentieth century [4], had his formal academic training in economics rather than medicine or statistics, and anticipated modern expected-net-benefit-based decision analysis [16]. He stated, 'finally, in passing from association to causation... we shall have to consider what flows from that decision' [8, p. 300], and suggested that the degree of evidence required, in so far as alternate explanations appear unlikely, depends on the potential costs and benefits of taking action. Recognizing the inevitable scientific uncertainty in establishing cause and effect, for Hill, the bottom line for causal inference – overlooked in most discussions of causation or statistical inference – was deciding whether the evidence was convincing enough to warrant a particular policy action when considering expected costs and benefits.

Histogram

A histogram is perhaps the graphical display that is used most often in the initial exploration of a set of measurements. Essentially, it is a simple graphical representation of a frequency distribution in which each class interval (category) is represented by a vertical bar whose base is the class interval and whose height is proportional to the number of observations in the class interval. When the class intervals are unequally spaced, the histogram is drawn in such a way that the area of each bar is proportional to the frequency for that class interval. Scott [1] considers how to choose the optimal number of classes in a histogram. Figure 1 shows a histogram of the murder rates (per 100 000) for 30 cities in southern USA in 1970.

The histogram is generally used for two purposes, counting and displaying the distribution of a variable, although it is relatively ineffective for both; **stem and leaf plots** are preferred for counting and **box plots** are preferred for assessing distributional properties. A histogram is the continuous data counterpart of the **bar chart**.

Historical Controls

Randomized trials (*see* **Clinical Trials and Intervention Studies**), in which a single group of units is randomly allocated to two or more treatment conditions and then studied in parallel over time, is the gold standard methodology for reducing biases. Yet not every comparison is amenable to a randomized trial. For example, one cannot randomize subjects to their genders or races. This implies that a comparison of men to women cannot be randomized. Furthermore, even some comparisons that could theoretically be amenable to study with a randomized trial would not be, for ethical reasons. For example, it is possible to randomly assign subjects to different numbers of cigarettes to be smoked per day in an effort to quantify the effects smoking would have on heart disease or lung cancer. Yet for ethical reasons such a study would be highly unlikely to be approved by an oversight committee.

Furthermore, even studies that could be conducted as randomized trials without much ethical objection may be conducted instead as historically controlled trials for financial reasons. For example, Phase II clinical trials often use historical data from the literature to compare the general response rate of experimental treatment to that of a standard treatment. The reality, then, is that some studies are nonrandomized. Nonrandomized studies may still be parallel over time, in that all treatment groups are treated and studied over the same time interval. For example, one could compare two treatments for headaches, both available over-the-counter, based on self-selected samples, that is, one would compare the experiences of those subjects who select one treatment against those subjects who select the other one. Such a design is susceptible to selection bias because those patients selecting one treatment may differ systematically from those selecting another [2, 5]. But at least such a design would not also confound treatments with time. Comparing the experiences of a group of subjects treated one way now to the experiences of a group of subjects treated another way at some earlier point in time has many of the same biases that the aforementioned self-selection design has, but it also confounds treatments and time, and hence introduces additional biases.

For example, suppose that a new surgical technique is compared to an old one by comparing the experiences of a group of subjects treated now with

the new technique to the experiences of a different group of subjects treated 10 years ago with the older technique. If the current subjects live longer or respond better in some other way, then one would want to attribute this to improvements in the surgical technique, and conclude that progress has been made. However, it is also possible that any observed differences are due to improvements not in the surgical technique itself but rather to improvements in ancillary aspects of patient care and management. Note that our interest is in comparing the experimental response rate to its counterfactual, or the response rate of the same subjects to the standard therapy. In a randomized trial, we substitute the experiences of a randomly selected control group for the counterfactual, and in a historically controlled trial, we substitute the experiences of a previously treated and nonrandomly selected control group for the counterfactual.

For a historically controlled trial to provide valid inference, then, we would need the response rate of the previously treated cohort to be the same as the response rate of the present cohort had they been treated with the standard treatment. One condition under which this would be true would be if the control response rate may be treated as a constant, independent of the cohort to which it is applied. Otherwise, use of historical controls may lead to invalid conclusions about experimental treatments [8]. Suppose, for example, that a new treatment is no better than a standard one, as each is associated with a 10% response rate in the population. One may even suppose that the same 10% of the population would respond to each treatment, so these are truly preordained responses, having nothing to do with which treatment is administered. Suppose that historical databases reveal this 10% response rate for the standard treatment, and now the new treatment is to be studied in a new cohort, using only the historical control group (no parallel concurrent control group).

Consider a certain recognizable subset of the population, based on specific values of measured covariates having not a 10% response rate but rather a 50% response rate. Moreover, suppose that this subgroup comprises 20% of the population, and none of the other 80% will respond at all. The overall response rate, then, is 50% of 20%, or the original 10%. A study of a given cohort would be representative of the overall population only to the

2 Historical Controls

extent that it is comprised of roughly 20% potential responders (those having the 50% response rate) and 80% nonresponders, following the population proportions. But if these proportions are distorted in the cohort, then the response rate in the cohort will not reflect the response rate in the population. In the extreme case, if the cohort is comprised entirely of potential responders, then the response rate will be 50%.

The key, though, is that if this distortion from the population is not recognized, then one might be inclined to attribute the increased response rate, 50% versus 10%, not to the composition of the sample but rather to how they were treated. One would go on to associate the 50% response rate with the new treatment, and conclude that it is superior to the standard one. We see that the selection bias discussed above can render historically controlled data misleading, so that observed response rates are not equal to the true response rates. However, historically controlled data can be used to help evaluate new treatments if selection bias can be minimized. The conditions under which selection bias can be demonstrated to be minimal are generally not very plausible, and require a uniform prognosis of untreated patients [3, 7]. An extreme example can illustrate this point. If a vaccine were able to confer immortality, or even the ability to survive an event that currently is uniformly fatal, then it would be clear, even without randomization, that this vaccine is effective. But this is not likely, and so it is probably safe to say that no historically controlled trial can be known to be free of biases.

Of course, if the evidentiary standard required for progress in science were an ironclad guarantee of no biases, then science would probably not make very much progress, and so it may be unfair to single out historically controlled studies as unacceptable based on the biases they may introduce. If historically controlled trials tend to be more biased than concurrent, or especially randomized trials, then this has to be a disadvantage that counts against historically controlled trials. However, it is not the only consideration. Despite the limitations of historical control data, there are, under certain conditions, advantages to employing this technique. For example, if the new treatment turns out to be truly superior to the control treatment, then finding this out with a historically controlled trial would not involve exposing any patients to the less effective control treatment [4].

This is especially important for patients with life-threatening diseases. Besides potential ethical advantages, studies with historical controls may require a smaller number of participants and may require less time than comparable randomized trials [4, 6].

If feasible, then randomized control trials should be used. However, this is not always the case, and historical control trials may be used as an alternative. The limitations of historical controls must be taken into account in order to prevent false conclusions regarding the evaluation of new treatments. It is probably not prudent to use formal inferential analyses with any nonrandomized studies, including historically controlled studies, because without a sample space of other potential outcomes and known probabilities for each, the only outcome that can be considered to have been possible (with a known probability, for inclusion in a sample space) is the one that was observed. This means that the only valid P value is the uninteresting value of 1.00 [1].

History of Analysis of Variance

Following its development by **Sir R.A. Fisher** in the 1920s, the **Analysis of Variance (ANOVA)** first reached a wide behavioral audience via Fisher's 1935 book, *The Design of Experiments* [4], a work that went through many editions and is frequently cited as the origin of behavioral science's knowledge of ANOVA. In fact, ANOVA was first used by an educational researcher in 1934 [10], based on earlier publications by Fisher. The incorporation of ANOVA was initially a gradual one, in which educational researchers and parapsychologists played the earliest roles, followed slightly later by experimental psychologists. Published applications of ANOVA remained few until after World War II, when its use accelerated rapidly. By the 1960s, it had become a routine procedure among experimental psychologists and had been incorporated as a required course in nearly all doctoral programs in psychology.

The history of ANOVA in the behavioral sciences is also the history of Fisherian ideas and of small sample statistics generally. Thus, although Student's t had been developed much earlier than ANOVA, its incorporation by behavioral scientists did not begin until the 1930s and its use grew in parallel to that of ANOVA [11]. This parallelism has been attributed to the incorporation of null hypothesis testing into a broader methodology of experimental design for which ANOVA techniques were especially suited.

The initial uses of statistics in the psychological sciences were primarily correlational and centered on what Danziger [3] characterized as the 'Galtonian' (see **Galton, Francis**) tradition. Statistical analysis was prominent, but the emphasis was upon the measurement of interindividual differences. There were few connections with experimental design methods during this period. The focus was upon variation, a key concept for the post-Darwinian functional approach of the Galtonians. Yet within psychology (as within eugenics) interest in variation was soon displaced by interest in the mean value, or central tendency, a change attributed to increasing bureaucratic pressure to characterize aggregates of people (as in school systems). During the first third of the twentieth century, the use of descriptive and correlational

statistical techniques thus spread rapidly, especially in educational psychology.

The dominant psychological use of statistics during the first decades of the twentieth century reflected a statistics 'without P values'. Such statistical applications were closely related to those prominent among sociological and economic users of statistics. Significance testing, as such, was not used in psychology prior to the adoption of ANOVA, which happened only after the publication of Fisher's 1935 book. Nonetheless, there were precursors to significance testing, the most common being use of the 'critical ratio' for comparing two means, defined as the difference between the means divided by the 'standard deviation.' The latter sometimes represented a *pooled* value across the two groups, although with N instead of $N - 1$ in the denominator. An excellent early account of the critical ratio, one that anticipated later discussions by Fisher of statistical tests, was given in 1909 by Charles S. Myers in his *Text-Book of Experimental Psychology* [8]. Note also that the critical ratio thus defined is nearly identical to the currently widely used measure of **effect size** *Cohen's d* .

The use of inferential statistics such as ANOVA did *not* replace the use of correlational statistics in psychology. Instead, correlational techniques, which were in use by psychologists almost from the establishment of the discipline in America, showed no change in their relative use in American psychological journals. Between 1935 and 1952, the use of correlational techniques remained steady at around 30% of all journal articles; during the same period, the use of ANOVA increased from 0 to nearly 20% and the use of the t Test increased from 0 to 32% [11]. While the relative use of correlational techniques did not change as a result of the incorporation of ANOVA, there was a decline in the use of the critical ratio as a test, which vanished completely by 1960. There was also a decline in the prominence given to 'brass and glass' instruments in psychological publications after World War II, in spite of a continuing ideological strength of experimentation. In fact, statistical analysis strengthened this ideology to a degree that instruments alone had not been able to do; statistics, including ANOVA, became the 'instruments of choice' among experimentalists.

It is also clear that the incorporation of ANOVA into psychology was not driven solely by the logical

need for a method of analyzing complex **experimental designs**. Lovie [7] noted that such designs were used long prior to the appearance of ANOVA techniques and that even **factorial** and nested designs were in occasional use in the 1920s and 1930s. He suggested that the late appearance of ANOVA was instead due in part to the cognitive complexity of its use and the relatively limited mathematical backgrounds of the experimental psychologists who were its most likely clients. Further, Lovie noted the deeply theoretical nature of the concept of **interaction**. Until the simplistic ‘rule of one variable’ that dominated experimental methodological thinking could be transcended, there was no proper understanding of the contribution that ANOVA could make.

In the United States, the demands of war research during World War II exposed many psychologists to new problems, new techniques, and a need to face the limitations of accepted psychological methods. In contrast to the first war, there was much less of the ‘measure everyone’ emphasis that characterized the Yerkes-led mental testing project of World War I. Instead, a variety of projects used the research abilities of psychologists, often in collaboration with other disciplinary scientists. War research also affected the nature of statistical analysis itself, and, in fact, also provided an opportunity for statisticians to establish their autonomy as a distinct profession. Many of the common uses of statistical inference were being extended by statisticians and mathematicians during the war, for example studies of bombing and fire control (**Neyman**), sequential analysis (Wald and others), and quality control statistics (**Deming**). More to the point, significance testing began to find its way into the specific applications that psychologists were working upon. Rucci & Tweney [11] found only 17 articles in psychology journals that used ANOVA between 1934 and 1939, and of these most of the applications were, as Lovie [7] noted, rather unimpressive. Yet the wartime experiences of psychologists drove home the utility of these procedures, led to many more psychologists learning the new procedures, and provided paradigmatic exemplars of their use.

After 1945, there was a rapid expansion of graduate training programs in psychology, driven in large part by a perceived societal need for more clinical and counseling services, and also by the needs of ‘Cold War’ military, corporate, and governmental bureaucracies. Experimental psychologists, newly apprised

of Fisherian statistical testing, and **measurement-oriented** psychologists who had had their psychometric and statistical skills sharpened by war research, were thus able to join hands in recommending that statistical training in *both* domains, ANOVA and correlational, be a requirement for doctoral-level education in psychology. As psychology expanded, experimental psychologists in the United States were therefore entrusted with ensuring the scientific credentials of the training of graduate students (most of whom had little background in mathematics or the physical sciences), even in clinical domains. The adoption of ANOVA training permitted a new generation of psychologists access to a set of tools of perceived scientific status and value, without demanding additional training in mathematics or physical science. As a result, by the 1970s, ANOVA was frequent in all experimental research, and the use of significance testing had penetrated all areas of the behavioral sciences, including those that relied upon correlational and **factor-analytic** techniques. In spite of frequent reminders that there were ‘two psychologies’ [2], one correlational and one ANOVA-based, the trend was toward the statistical merging of the two via the common embrace of significance testing.

In the last decades of the twentieth century, ANOVA techniques displayed a greater sophistication, including repeated measures designs (*see* **Repeated Measures Analysis of Variance**), mixed designs, **multivariate analysis of variance** and other procedures. Many of these were available long before their incorporation in psychology and other behavioral sciences. In addition, recent decades have seen a greater awareness of the formal identity between ANOVA and **multiple linear regression** techniques, both of which are, in effect, applications of a **generalized linear model** [9].

In spite of this growing sophistication, the use of ANOVA techniques has not always been seen as a good thing. In particular, the ease with which complex statistical procedures can be carried out on modern desktop computers has led to what many see as the misuse and overuse of otherwise powerful programs. For example, one prominent recent critic, Geoffrey Loftus [6], has urged the replacement of null hypothesis testing by the pictorial display of experimental effects, together with relevant **confidence intervals** even for very complex designs.

Many of the criticisms of ANOVA use in the behavioral sciences are based upon a claim that

inferential canons are being violated. Some have criticized the ‘mechanized’ inference practiced by many in the behavioral sciences, for whom a significant effect is a ‘true’ finding and a nonsignificant effect is a finding of ‘no difference’ [1]. Gigerenzer [5] argued that psychologists were using an incoherent ‘hybrid model’ of inference, one that inappropriately blended aspects of **Neyman/Pearson** approaches with those of Fisher. In effect, the charge is that a kind of misappropriated Bayesianism (see **Bayesian Statistics**) has been at work, one in which the P value of a significance test, $p(D|H_0)$, was confused with the *posterior* probability, $p(H_0|D)$, and, even more horribly, that $p(H_1|D)$ was equated with $1 - p(D|H_0)$. Empirical evidence that such confusions were rampant – even among professional behavioral scientists – was given by **Tversky & Kahneman** [12].

By the beginning of the twenty-first century, the ease and availability of sophisticated ANOVA techniques continued to grow, along with increasingly powerful graphical routines. These hold out the hope that better uses of ANOVA will appear among behavioral sciences. The concerns over mechanized inference and inappropriate inferential beliefs will not, however, be resolved by any amount of computer software. Instead, these will require better methodological training and more careful evaluation by journal editors of submitted articles.

History of Behavioral Statistics

If we follow Ian Hacking [4] and conclude that modern ideas about probability emerged a little less than 300 years ago, and that other historians have pointed to the nineteenth century as the start of statistics proper, then it is clear that statistical analysis is a very recent phenomenon indeed. Further, if one also follows historians like Mackenzie [8] and Porter [9], then modern statistics began in Britain and was a feature of the last half of the nineteenth century only. Of course, the collection of data relating to social, economic, and political concerns was of interest to many people of a wide ideological hue in many countries much earlier on in the nineteenth century, as did the reduction of such material to tabular and graphical forms, but there were no officially blessed attempts to draw conclusions from these exercises or to establish any causal links between the material, although there were plenty of amateur efforts to do so. Indeed, the 1838 motto of the London Statistical Society: '*Aliis exterendum*' ('to be threshed out by others'), together with its pledge 'to exclude all opinion' gives one a feel for the extreme empiricism of the so-called *statists* of the time. However, this rule was not one that sprang from mere conviction, but was designed to placate those who argued that drawing conclusions from such potentially explosive material would create such dissent that the Society would split asunder. What seemed to create a change to the more analytical work of figures such as **Francis Galton** and **Karl Pearson** in the nineteenth century, and **R A Fisher** in the twentieth, was the European work on probability by **Laplace** toward the end of the eighteenth century, and the realization by figures such as **Quetelet** that it could be applied to social phenomena. In other words, such developments were spurred on by the near-simultaneous acceptance that the world was fundamentally uncertain, *and* the recognition of the key role of probability theory in defining and managing such an unpredictable situation.

Thus, once it is accepted that the world is fundamentally uncertain and unpredictable, as was increasingly the case during the nineteenth century, then the means for confronting the reality that *nothing* can be asserted or trusted absolutely or unconditionally had

to be urgently conceived. And this was particularly true of the nascent field of statistics, since its ostensive business was the description and management of an uncertain world. In practice, this did not turn out to be an impossible task, although it took a great deal of time and effort for modern statistical thinking and action to emerge. I want to argue that this was achieved by creating a structure for the world which managed the chaotic devil of uncertainty by both constraining and directing the actions and effects of uncertainty. But this could only be achieved through extensive agreement by the principle players as to what was a realistic version of the world and how it's formal, that is, mathematical, description could be derived. This also went hand in hand with the development of workable models of uncertainty itself, with the one feeding into the other. And it is also the case that many of these structural/structuring principles, for example, the description of the world in terms of variables with defined (or even predefined) properties, were taken over by psychology from much earlier scientific traditions, as was the notion (even the possibility) of systematic and controlled experimentation.

Let me briefly illustrate some of these ideas with Adolphe Quetelet's distinction between a true average and an arithmetic average, an idea that he developed in 1846. This was concerned with choosing not just the correct estimator, but also constraining the situation so that what was being measured was in some senses homogeneous, hence any distribution of readings could be treated as an error distribution (a concept that Quetelet, who started out as an astronomer, would have been familiar with from his earlier scientific work). Thus, collecting an unsorted set of houses in a town, measuring them once and then calculating an average height would yield little information either about the houses themselves or about the height of a particular house. On the other hand, repeatedly measuring the height of one house would, if the measurements were not themselves subject to systematic bias or error, inevitably lead to the true average height for that house. In addition, the set of readings would form a distribution of error around the true mean, which could itself be treated as a probability distribution following its own 'natural law'. Notice the number of hidden but vital assumptions here: first, that a house will remain the same height for a reasonable length of time, hence the measurements are of a homogenous part of the

world; second, that height is a useful property of a house that can be expressed as a measurable variable; third, that the measurements are not biased in any way during their collection, hence any variation represents pure error around the true height and not a variation in the height of the building itself; and finally, that the estimator of height has certain useful properties, which commends it to the analyst. Thus, one has a mixture of consensually achieved background ideas about the context, how the particular aspect of interest can be experimentally investigated, and agreement as to what summary numbers and other representations of the sample yield the most useful information. Statistics is about all of these, since all of them affect how any set of numbers is generated and how they are interpreted.

When we move on quickly to the middle and latter parts of the nineteenth century we find that Quetelet's precepts have been accepted and well learnt (although not perhaps his radical social physics, or his emphasis on *l'homme moyen*, or the average man), and that people are now more than happy to draw conclusions from data, since they are convinced that their approach warrants them to do so. Thus, Galton is happy to use the emerging methods of regression analysis to argue a hereditarian case for all manner of human properties, not just his famous one of heights. Karl Pearson's monumental extension and elaboration of both Galton's relatively simple ideas about relationships and his rather plain vanilla version of Darwinian evolution marks the triumph of a more mathematical look to statistics, which is now increasingly seen as the province of the data modeler rather than the mere gatherer-in of numbers and their tabulation. This is also coincident, for example, with a switch from individual teaching and examining to mass education and testing in the schools, thus hastening the use of statistics in psychology and areas related to it like education (see [2], for more information). One cannot, in addition, ignore the large amount of data generated by psychophysicists like **Fechner** (who was a considerable statistician in his own right), or his model building in the name of *panpsychism*, that is, his philosophy that the whole universe was linked together by a form of psychic energy. The 1880s and 1890s also saw the increasing use of systematic, multifactor experimental designs in the psychological and pedagogical literature, including several on the readability of print. In other words, there was an unrequited thirst in psychology for more

quantitative analyses that went hand in hand with how the psychologist and the educational researcher viewed the complexity of their respective worlds.

The first decade or so of the twentieth century also saw the start of the serious commitment of psychology to statistical analysis in so far as this marks the publication of the first textbooks in the subject by popular and well-respected authors like Thorndike. There was also a lively debate pursued by workers for over 30 years as to the best test for the difference between a pair of means. This had been kick started by Yerkes and Thorndike at the turn of the century and had involved various measures of variation to scale the difference. This was gradually subsumed within Student's *t* Test, but the existence of a range of solutions to the problem meant that, unlike **analysis of variance (or ANOVA)**, the acceptance of the standard analysis was somewhat delayed, but notice that the essentially uncertain nature of the world and any data gathered from it had been explicitly recognized by psychologists in this analysis (see [7] for more details). Unfortunately, the major twentieth-century debates in statistics about inference seemed to pass psychology by. It was only in the 1950s, for example, that the Neyman–Pearson work on Type I and II errors (see **Neyman–Pearson Inference**) from the 1930s had begun to seep into the textbooks (see [7], for a commentary as to why this might have been). An exception could possibly be made for Bayesian inference and its vigorous take up in the 1960s by Ward Edwards [3] and others (see his 1963 paper, for instance), but even this seemed to peter out as psychology came to reluctantly embrace power, sample size, and effects with its obvious line to a Neyman–Pearson analysis of inference. Again, such an analysis brings a strong structuring principle and worldview to the task of choosing between uncertain outcomes.

The other early significant work on psychological statistics, which simultaneously both acknowledged the uncertain nature of the world and sought structuring principles to reduce the effects of this uncertainty was **Charles Spearman's** foray into **factor analysis** from 1904 onwards. Using an essentially **latent variable** approach, Spearman looked for support for the strongly held nineteenth-century view that human nature could be accounted for by a single general factor (sometimes referred to as *mental energy*) plus an array of specific factors whose operation would be determined by the individual demands of the situation

or task. This meant that a hierarchical structure could be imposed, *a priori*, on the intercorrelations between the various scholastic test results that Spearman had obtained during 1903. Factor analysis as a deductive movement lasted until the 1930s when the scepticism of **Godfrey Thomson** and the risky, inductive philosophy of Louis Thurstone combined to turn factor analysis into the exploratory method that it has become today (see [7], and [1], for more detail). But notice that the extraction of an uncertainty-taming *structure* is still the aim of the enterprise, whatever flavor of factor analysis we are looking at. And this is also the case for all the multivariable methods, which were originated by Karl Pearson, from **principal component analysis** to **multiple linear regression**.

My final section is devoted to a brief outline of the rapid acceptance by psychology of the most widely employed method in psychological statistics, that is, ANOVA (see [1, 5, 6, 10] for much more detail). This was a technique for testing the differences between more than two samples, which was developed in 1923 by the leading British statistician of this time, R A Fisher, as part of his work in agricultural research. It was also a method which crucially depended for its validity on the source of the data, specifically from experiments that randomly allocated the experimental material, for instance, varieties of wheat, to the experimental plots. Differences over the need for random allocation was the cause of much bitterness between Fisher and 'Student' (**W S Gosset**), but it is really an extension of Quetelet's rule that any variation in the measurement of a homogenous quality such as a single wheat variety should reflect error and nothing else, a property that only random allocation could guarantee. In psychology, ANOVA and its extension to more than one factor were quickly taken into the discipline after the appearance of Fisher's first book introducing the method (in 1935), and was rapidly applied to the complex, multifactor experiments, which psychology had been running for decades. Indeed, so fast was this process that Garrett and Zubin, in 1943, were able to point to over 30 papers and books that used ANOVA and

variations, while the earliest example that I could find of its application to an area close to psychology was by the statistician Reitz who, in 1934, used the technique to compare student performance across schools. Clearly, psychology had long taken people's actions, beliefs, and thought to be determined by many factors. Here at last was a method that allowed them to quantitatively represent and explore such a structuring worldview.

History of the Control Group

A Special Kind of Group

Currently, anyone with a qualification in social science (and also medicine) takes the notion of the 'control group' for granted. Yet, when one comes to think of it, a control group is an exceptional kind of group. Usually, the notion of a 'group' refers to people sharing a particular identity or aim, having a sense of oneness, and most likely also a group leader. Members of control groups, however, do not even need to know one another. One may run into groups of tourists, teenagers, hikers, or hooligans, but never a group of controls. Different from groups in the regular sense, control groups are merely a number of people. They do not exist outside the realm of human science experimentation, and *qua* group, they exist only in the minds of the experimenters who compose and study them. Members of control groups are not supposed to develop group cohesion because that would entail a contaminating factor in the experiment. Researchers are interested in the average response of individual members rather than in their behavior as a group (see **Clinical Trials and Intervention Studies**).

Control groups serve to check the mean effectiveness of an intervention. In order to explain their need, a methods teacher will first suggest that if a particular person shows improvement this does not yet guarantee effectiveness in other people too. Therefore, a number of people must be studied and their average response calculated. This, however (the teacher will proceed), would not be enough. If we know the average result for one group of people, it remains unclear whether the intervention caused the outcome or a simultaneous other factor did. Only if the mean result of the group differs significantly from that of an untreated control group is the conclusion justified that the treatment caused the effect (or, more precisely, that the effect produced was not accidental).

Apart from the idea of comparing group averages, the notion of the true control group entails one pivotal extra criterion. The experimental and control groups must be comparable, that is, the former should not differ from the latter except through the action of

the independent variable that is to be tested. One option is to use the technique of 'matching', that is, to pretest people on factors suspected of causing bias and then create groups with similar test results. Most contemporary methodologists, however, agree that random assignment of the participants to the groups offers a better guarantee of comparability. Assigning people on the basis of chance ensures that both known and unknown invalidating factors are cancelled out, and that this occurs automatically rather than being dependent on individual judgment and trustworthiness. In behavioral and social (as well as clinical) research, the ideal scientific experiment is a so-called *randomized controlled trial*, briefly an RCT.

In view of its self-evident value, and in view of the extensive nineteenth-century interest in human science experimentation, the introduction of the control group may strike us as being remarkably late. Until the early 1900s, the word control was not used in the context of comparative experiments with people, whereas ensuring comparability by matching dates back to the 1910s, and composing experimental and control groups at random was first suggested as late as the 1920s.

The present history connects the seemingly late emergence of the control group to its special nature as a group without a shared extra-individual identity. Moreover, it explains that such groups were inconceivable before considerable changes occurred in society at large. First, however, we need to briefly explain why famous examples of comparison such as that of doctor Ignaz Semmelweis, who fought childbed fever by comparing two maternity clinics in mid-nineteenth-century Vienna [23], are not included in the present account.

The Past and the Present

Comparison is 'a natural thing to do' to anyone curious about the effects of a particular action. Therefore, it should not come as a surprise that instances of comparison can also be found in the long history of interventions into human life. In a scholarly article on the history of experimentation with medical treatments, Ted Kaptchuck discussed various eighteenth-century procedures of comparison (although not to similar groups) such as the deliberately deceptive provision of bread and sugar pills

2 History of the Control Group

to check the claims of homeopathy [24]. And several examples of group comparison in the treatment of illnesses (although without randomization) are also presented in the electronic *James Lind Library* (www.jameslindlibrary.org).

Entertaining, however, as such examples of comparison may be, they are hardly surprising, since checking the effects of one's actions by sometimes withholding them is a matter of everyday logic. Moreover, it would be quite artificial to depict these examples as early, if still incomplete, steps toward the present-day methodological rule of employing control groups. Historians of science use derogatory labels such as 'presentist history', 'finalist history', 'justificationary history', and 'feel good history', for histories applying present-day criteria in selecting 'predecessors' who took 'early steps' toward our own viewpoints, whilst also excusing these 'pioneers' for the understandable shortcomings still present in their ideas. Arranging the examples in chronological order, as such histories do, suggests a progressive trajectory from the past to the present, whereas they actually drew their own line from the present back into the past. Historian and philosopher of science Thomas Kuhn discussed the genre under the name of 'preface history', referring to the typical historical introduction in textbooks. Apart from worshipping the present, Kuhn argued, preface histories convey a deeply misleading view of scientific development as a matter of slow, but accumulative, discovery by a range of mutually unrelated great men [25, pp. 1–10; 136–144].

Rather than lining up unconnected look-alikes through the ages, the present account asks when, why, and how employing control groups became a methodological condition. The many reputed nineteenth-century scholars who explicitly *rejected* experimental comparison are neither scorned nor excused for their 'deficiency'. Rather, their views are analyzed as contributions to debates in their own time. Likewise, the ideas of early twentieth-century scholars who advanced group comparison are discussed as part of debates with their own contemporaries.

Nineteenth-century Qualms

If control groups were not recommended before the early twentieth century, the expression of "social experimentation" did appear in much earlier methodological texts. Eighteenth-century scholars had

already discussed the issue of experimentation as a suitable method for investigating human life [7]. David Hume's *Treatise of Human Nature*, first published in 1739, is subtitled: *Being an Attempt to Introduce the Experimental Method of Reasoning into Moral Subjects*. Hume and his Enlightenment contemporaries, however, borrowed the terminology of experimentation from natural science as a metaphor for major events happening without the intervention of researchers. Observing disturbances of regular life, they argued, is the human science substitute of natural science experimentation.

Nineteenth-century views on social experimentation were largely, but not entirely, the same as those of the eighteenth century. Distinguished scholars such as **Adolphe Quetelet** (1796–1874) in Belgium, Auguste Comte (1798–1857) in France, and George Cornwall Lewis (1806–1863) as well as John Stuart Mill (1806–1873) in Britain used the terminology of experimentation for incidents such as natural disasters, famines, economic crises, and also government interventions. Different, however, from eighteenth-century scholars and in accordance with later twentieth-century views, they preserved the epithet of *scientific* experimentation for experiments with active manipulation by researchers. As scientific experimentation entails intentional manipulation by researchers, they maintained, research with human beings cannot be scientific.

Roughly speaking, there were two reasons why they excluded deliberate manipulation from the useable methods of research with human beings. One reason was of a moral nature. When George Cornwall Lewis in 1852 published his two-volume *Treatise on the Methods of Observation and Reasoning in Politics*, he deliberately omitted the method of experimentation from the title. Experimentation, Lewis maintained, is 'inapplicable to man as a sentient, and also as an intellectual and moral being'. This is not 'because man lies beyond the reach of our powers', but because experiments 'could not be applied to him without destroying his life, or wounding his sensibility, or at least subjecting him to annoyance and restraint' [26, pp. 160–161].

The second reason was of an epistemological nature. In 1843, the prominent British philosopher, economist, and methodologist John Stuart Mill published his *System of Logic* that was to become very influential in the social sciences. This work extensively discussed Mill's 'method of difference', which

entailed comparing cases in which an effect does and does not occur. According to Mill, this ‘most perfect of the methods of experimental inquiry’ was not suitable for research with people. He illustrated this view with the ‘frequent topic of debate in the present century’, that is, whether or not government intervention into free enterprise impedes national wealth. The method of difference is unhelpful in a case like this, he explained, because comparability is not achievable: ‘[I]f the two nations differ in this portion of their institutions, it is from some differences in their position, and thence in their apparent interests, or in some portion or the other of their opinions, habits and tendencies; which opens a view of further differences without any assignable limit, capable of operating on their industrial prosperity, as well as on every other feature of their condition, in more ways than can be enumerated or imagined’ [31, pp. 881–882].

Mill raised the objection of incomparability not only in complex issues such as national economic policies but in relation to all research with people. Even a comparatively simple question such as, whether or not mercury cures a particular disease, was ‘quite chimerical’ as it was impossible in medical research to isolate a single factor from all other factors that might constitute an effect. Although the efficacy of ‘quinine, colchicum, lime juice, and cod liver oil’ was shown in so many cases ‘that their tendency to restore health... may be regarded as an experimental truth’, real experimentation was out of the question, and ‘[S]till less is this method applicable to a class of phenomena more complicated than those of physiology, the phenomena of politics and history’ [31, pp. 451–452].

Organicism and Determinism

How to explain the difference between these nineteenth-century objections and the commonness of experimentation with experimental and control groups in our own time? How could Lewis be compunctious about individual integrity even to the level of not ‘annoying’ people, whereas, in our time, large group experiments hardly raised an eyebrow? And why did a distinguished methodologist like Mill not promote the solution, so self-evident to present-day researchers, of simply *creating* comparable groups if natural ones did not exist?

The answer is that their qualms were inspired by the general holism and determinism of their time. Nineteenth-century scholars regarded communities as well as individuals as organic systems in which every element is closely related to all others, and in which every characteristic is part of an entire pattern of interwoven strands rather than caused by one or more meticulously isolated factors. In addition, they ascribed the facts of life to established laws of God or Nature rather than to human purposes and plans. According to nineteenth-century determinism, the possibilities of engineering human life were very limited. Rather than initiating permanent social change, the role of responsible authorities was to preserve public stability. Even Mill, for whom the disadvantages of a *laissez-faire* economy posed a significant problem, nevertheless, held that government interference should be limited to a small range of issues and should largely aim at the preservation of regular social order.

In this context, the common expression of ‘social experimentation’ could not be more than a metaphor to express the view that careful observation of severe disturbances offers an understanding of the right and balanced state of affairs. The same holistic and determinist philosophy expressed itself in nineteenth-century statistics, where indeterminism or chance had the negative connotation of lack of knowledge and whimsicality rather than the present-day association of something to ‘take’ and as an instrument to make good use of [33, 22]. Nineteenth-century survey researchers, for instance, did not draw representative population samples. This was not because of the inherent complexity of the idea, nor because of sluggishness on the researchers’ part, but because they investigated groups of people as organic entities and prototypical communities [17]. To nineteenth-century researchers, the idea of using chance for deriving population values, or, for that matter, allocating people to groups, was literally unimaginable.

Even the occasional proponent of active experimentation in clinical research rejected chance as an instrument of scientific research. In 1865, the illustrious French physiologist Claude Bernard (1813–1878) published a book with the deliberately provocative title of *Introduction à L’étude de la Médecine Expérimentale* [1] translated into English as *An Introduction to the Study of Experimental Medicine*. Staunchly, Bernard stated that ‘philosophic obstacles’

4 History of the Control Group

to experimental medicine ‘arise from vicious methods, bad mental habits, and certain false ideas’ [2, p. 196]. For the sake of valid knowledge, he maintained, ‘comparative experiments have to be made at the same time and on as comparable patients as possible’ [2, p. 194].

Yet, one searches Bernard’s *Introduction* in vain for comparison of experimental to control groups. As ardently as he defended experimentation, he rejected statistical averages. He sneered about the ‘startling instance’ of a physiologist who collected urine ‘from a railroad station urinal where people of all nations passed’ as if it were possible to analyze ‘the *average* European urine!’ (italics and exclamation mark in original). And he scorned surgeons who published the success rates of their operations because average success does not give any certainty on the next operation to come. Bernard’s expression of ‘comparative experimentation’ did refer to manipulating animals and humans for the sake of research. Instead of comparing group averages, however, he recommended that one should present ‘our most perfect experiment as a type’ [2, pp. 134–135]. To Bernard, the rise of probabilistic statistics meant ‘literally nothing scientifically’ [2, p. 137].

Impending Changes

The British statistician, biometrician, and eugenicist **Sir Francis Galton** (1822–1911) was a crucial figure in the gradual establishment of probabilism as an instrument of social and scientific progress. Galton was inspired by Adolphe Quetelet’s notion of the statistical mean and the normal curve as a substitute for the ideal of absolute laws. In Quetelet’s own writings, however, this novelty was not at odds with determinism. His well-known *L’homme moyen* (average man) represented normalcy and dispersion from the mean signified abnormality. It was Galton who gave Quetelet’s mean a progressive twist.

Combining the evolution theory of his cousin Charles Darwin with eugenic ideals of human improvement, Galton held that ‘an average man is morally and intellectually a very uninteresting being. The class to which he belongs is bulky, and no doubt serves to keep the course of social life in action... But the average man is of no direct help towards evolution, which appears to our dim vision to be the

primary purpose, so to speak, of all living existence’, whereas ‘[E]volution is an unrelenting progression,’ Galton added, ‘the nature of the average individual is essentially unprogressive’ [20, p. 406].

Galton was interested in finding more ways of employing science for the sake of human progress. In an 1872 article ‘Statistical Inquiries into the Efficacy of Prayer’, he questioned the common belief that ‘sick persons who pray, or are prayed for, recover on the average more rapidly than others.’ This article opened with the statement that there were two methods of studying an issue like the profits of piety. The first one was ‘to deal with isolated instances’. Anyone, however, using that method should suspect ‘his own judgments’ or otherwise would ‘certainly run the risk of being suspected by others in choosing one-sided examples’. Galton vigorously broke a lance for substituting the study of representative types with statistical comparison. The most reliable method was ‘to examine large classes of cases, and to be guided by broad averages’ [19, p. 126].

Galton elaborately explained how the latter method could be applied in finding out the revenues of praying: ‘We must gather cases for statistical comparison, in which the same object is keenly pursued by two classes similar in their physical but opposite in their spiritual state; the one class being spiritual, the other materialistic. Prudent pious people must be compared with prudent materialistic people and not with the imprudent nor the vicious. We simply look for the final result - whether those who pray attain their objects more frequently than those who do not pray, but who live in all other respects under similar conditions’ [19, p. 126].

As it seems, Galton was the first to advocate comparison of group averages. Yet, his was not an example of treating one group while withholding the treatment from a comparison group. The emergence of the control group in the present-day sense occurred when his fears of ‘being suspected by others in choosing one-sided examples’ began to outgrow anxieties on doing injustice to organic wholes. This transition took place with the general changeover from determinism to progressivism in a philosophical as well as social sense.

Progressivism and Distrust

By the end of the nineteenth century, extreme destitution among the working classes led to social

movements for mitigation of *laissez faire* capitalism. Enlightened members of the upper middle class pleaded for some State protection of laborers via minimum wage bills, child labor bills, and unemployment insurances. Their appeals for the extension of government responsibility met with strong fears that help would deprive people of their own responsibility and that administrations would squander public funds. It was progressivism combined with distrust that constituted a new definition of social experimentation as statistical comparison of experimental and control groups. Three interrelated maxims of twentieth-century economic liberalism were crucial to the gradual emergence of the present-day ideal experiment.

The first maxim was that of *individual responsibility*. Social success and failure remained an individual affair. This implied that ameliorative attempts were to be directed first and foremost at problematic individuals rather than on further structural social change. Helping people implied trying to turn them into independent citizens by educating, training, punishing, and rewarding them. The second maxim was that of *efficiency*. Ameliorative actions financed with public money had to produce instant results with simple economical means. The fear that public funds would be squandered created a strong urge to attribute misery and backwardness to well-delineated causes rather than complex patterns of individual and social relations. And the third maxim was that of *impersonal procedures*. Fears of abuse of social services evoked distrust of people's own claims of needs, and the consequent search for impersonal techniques to establish the truth 'behind' their stories [38]. In addition, not only was the self-assessment of the interested recipients of help to be distrusted but also that of the politicians and administrators providing help. Measurement also had to control administrators' claims of efficiency [34].

Academic experts on psychological, sociological, political, and economical matters adapted their questions and approaches to the new demands. They began to produce technically useful data collected according to standardized methodological rules. Moreover, they established a partnership with statisticians who now began to focus on population varieties rather than communalities. In this context, the interpretation of chance as something one must make good use of replaced the traditional one of chance as something to defeat [17, 22, 33].

The new social scientists measured people's abilities, motives, and attitudes, as well as social phenomena such as crime, alcoholism, and illiteracy. Soon, they arrived at the idea that these instruments could also be used for establishing the results of ameliorative interventions. In 1917, the well-reputed sociologist F. Stuart Chapin lengthily discussed the issue. Simple, before and after measurement of one group, he stated, would not suffice for excluding personal judgement. Yet, Chapin rejected comparison of treated and untreated groups. Like Mill before him, he maintained that fundamental differences between groups would always invalidate the conclusions of social experiments. Adding a twentieth-century version to Lewis' moral objections, he argued that it would be immoral to withhold help from needy people just for the sake of research [9, 10]. It was psychologists who introduced the key idea to create equal groups rather than search for them in natural life, and they did so in a context with few ethical barriers.

Creating Groups

Psychologists had a tradition of psychophysiological experimentation with small groups of volunteers in laboratory settings for studying the law-like relationships between physical stimuli and mental sensations. During the administrative turn of both government and human science, many of them adapted their psychophysiological methods to the new demands of measuring progress rather than just discovering laws [14, 15]. One of these psychologists was John Edgar Coover, who studied at Stanford University in Palo Alto (California) with the psychophysical experimenter Frank Angell. As a former school principal, Coover gave Angell's academic interests an instrumental twist. He engaged in a debate among school administrators on the utility of teaching subjects such as Latin and formal mathematics. Opponents wanted to abolish such redundant subjects from the school curriculum, but proponents argued that 'formal discipline' strengthens general mental capacities. Coover took part in this debate with laboratory experiments testing whether or not the training of one skill improves performance in another ability. In a 1907 article, published together with Angell, he explained that in the context of this kind of research a one-group design does not do. Instead, he compared the achievements of experimental 'reagents'

who received training with those of control ‘reagents’ who did not [13]. Coover and Angell’s article seems to be the first report of an experiment in which one group of people is treated and tested, while another one is only tested.

From the 1910s, a vigorous movement started in American schools for efficiency and scientific (social) engineering [6]. In the school setting, it was morally warrantable and practically doable to compare groups. Like the earlier volunteers in laboratories, school children and teachers were comparatively easy to handle. Whereas historian Edwin Boring found no control groups in the 1916 volume of the *American Journal of Psychology* [3, page 587], historian Kurt Danziger found 14 to 18% in the 1914–1916 volumes of the *Journal of Educational Psychology* [14, pp. 113–115].

Psychological researchers experimented in real classrooms where they tested the effects of classroom circumstances such as fresh versus ventilated air, the sex of the teacher, memorizing methods, and educational measures such as punishing and praising. They also sought ways of excluding the possibility that their effects are due to some other difference between the groups than the variable that is tested. During the 1920s, it became customary to handle the problem by matching. Matching, however, violated the guiding maxims of efficiency and impersonality. It was quite time- and money-consuming to test each child on every factor suspected of creating bias. And, even worse, determining these factors depended on the imaginative power and reliability of the researchers involved. Matching only covered possibly contaminating factors that the designers of an experiment were aware of, did not wish to neglect, and were able to pretest the participants on.

In 1923, William A. McCall at Columbia University in New York, published the methodological manual *How to Experiment in Education* in which he emphasized the need of comparing similar groups [30]. In the introduction to this volume, McCall predicted that enhancing the efficiency of education could save billions of dollars. Further on, he proposed to equate the groups on the basis of chance as ‘an economical substitute’ for matching. McCall did not take randomization lightly. For example, he rejected the method of writing numbers on pieces of paper because papers with larger numbers contain more ink and are therefore likely to sink further to the bottom of a container. But, he stated, ‘any

device which will make the selection truly random is satisfactory’ [30, pp.41–42].

Fisher’s Support

In the meantime, educational psychologists were testing various factors simultaneously, which made the resulting data hard to handle. The methodological handbook *The Design of Experiments* published in 1935 by the British biometrician and agricultural statistician **Ronald A. Fisher** provided the solution of **analysis of variance (ANOVA)**. As Fisher repeatedly stressed, random allocation to groups was a central condition to the validity of this technique. When working as a visiting professor at the agricultural station of Iowa State College, he met the American statistician **George W. Snedecor**. Snedecor published a book based on Fisher’s statistical methods [37] that was easier to comprehend than Fisher’s own, rather intricate, writings and that was widely received by methodologists in biology as well as psychology [28, 35]. Subsequently, Snedecor’s Iowa colleague, the educational psychologist Everett Lindquist, followed with the book *Statistical Analysis in Educational Research* which became a much-cited source in the international educational community [27].

Fisher’s help was welcomed with open arms by methodologists, not only because it provided a means to handle multi factor research but also because it regulated experimentation from the stage of the experimental design. As Snedecor expressed it in 1936, the designs researchers employed often ‘bafled’ the statisticians. ‘No more than a decade past, the statistician was distinctly on the defence’, he revealed, but ‘[U]nder the leadership of R. A. Fisher, the statistician has become the aggressor. He has found that the key to the problem is the intimate relation between the statistical method and the experimental plan’ [36, p. 690]. This quote confirms the thesis of historians that the first and foremost motive to prescribe randomization was not the logic of probabilistic statistics, but the wish to regulate the conduct of practicing researchers [8, 16, 29, 34]. Canceling out personal judgment, together with economical reasons, was the predominant drive to substitute matching by randomization. Like Galton in 1872, who warned against eliciting accusations of having chosen one-sided examples, early twentieth-century

statisticians and methodologists cautioned against the danger of selection bias caused by high hopes on particular outcomes.

Epilogue

It took a while before **randomization** became more than a methodological ideal. Practicing physicians argued that the hopes of a particular outcome are often a substantial part of the treatment itself. They also maintained that it is immoral to let chance determine which patients gets the treatment his doctor believes in and which patient does not, as well as keeping it a secret as to which group a patient has been assigned. Moreover, they put forward the argument that subjecting patients to standardized tests rather than examining them in a truly individual way would harm, rather than enhance, the effectiveness of diagnoses and treatments.

In social research, there were protests too. After he learned about the solution of random allocation, sociologist F. Stuart Chapin unambiguously rejected it. Allocating people randomly to interventions, he maintained, clashes with the humanitarian mores of reform [11, 12]. And the Russian-American anthropologist Alexander Goldenweiser objected that human reality ‘resents highhanded manipulation’ for which reason it demands true dictators to ‘reduce variety by fostering uniformity’ [21, p. 631]. An extensive search for the actual use of random allocation in social experiments led to the earliest instance in a 1932 article on educational counseling of university students, whereas the next seven appeared in research reports dating from the 1940s (all but one in the field of educational psychology) [18].

Nevertheless, the more twentieth-century welfare capitalism replaced nineteenth-century *laissez-faire* capitalism, the more administrators and researchers felt that it is both necessary and morally acceptable to experiment with randomized groups of children as well as adults. From about the 1960s onward, therefore, protesting doctors could easily be accused of an unwillingness to give up an outdated elitist position for the truly scientific attitude. Particularly in the United States, the majority of behavioral and social researchers too began to regard experiments with randomly composed groups as the ideal experiment. Since President Johnson’s War on Poverty, many such social experiments have been conducted, sometimes with thousands of people. Apart from school

children and university students, also soldiers, slum dwellers, spouse beaters, drug abusers, disabled food-stamp recipients, bad parents, and wild teenagers have all participated in experiments testing the effects of special training, social housing programs, marriage courses, safe-sex campaigns, health programs, income maintenance, employment programs, and the like, in an impersonal, efficient, and standardized way [4, 5, 32].

History of Correlational Measurement

Shakespeare in *Julius Caesar* avers, ‘Yond Cassius has a lean and hungry look; He thinks too much. Such men are dangerous.’ This and more mundane generalities, such as, ‘Like father, like son,’ have been quoted for centuries. They illustrate perceived relationships between both different and similar variables, as in those between offspring and parental characteristics. However, it was not until the nineteenth century that attempts began to quantify such relationships, work that is generally attributed to **Sir Francis Galton** (1822–1911) and his disciple and friend, **Karl Pearson** (1857–1936).

However, a number of mathematicians had worked on the measurement of the relationships among variables. Helen Walker [5] has observed that Plana, Adrain, **Gauss**, and **Laplace** examined probabilities in the context of the simultaneous occurrence of pairs of errors, and formulae that included a product term were suggested. De Forest and Czuber also discussed the problem. This work took place in the context of the *Law of Frequency of Error*, now termed the *normal distribution*. It is not too surprising that the mathematics of error estimation were adopted by social scientists especially when **Quetelet** equated error with the deviations from the mean of many measured human and characteristics.

But perhaps the best-known writer in the field was a French mathematician who was examining the question of error estimation in the context of astronomy, although it was treated as a mathematical exercise rather than the development of a practical statistical tool. Auguste Bravais formulated a mathematical theory, and published a lengthy paper on the matter in 1846, but apparently failed to appreciate that the topic had wider application than in the fields of astronomy [1]. Also, land surveying, physics, and gambling problems were recognized as having relevance to the estimation of errors and pairs of errors. However, Bravais’ work has been suggested as the natural precursor to Karl Pearson’s work, at least until as recently as the 1960s and beyond. What we now commonly refer to as **Pearson’s product-moment coefficient** was called the *Bravais–Pearson coefficient* by some researchers.

What is more, in 1896, Pearson himself acknowledged Bravais’ work in the paper that gave us the product-moment coefficient, but later denied that he had been helped by his contribution. But, it would be foolish to reject Bravais’ work for it is certainly the earliest most complete account of the mathematical foundations of the correlation coefficient.

In 1892, Edgeworth examined correlation and methods of estimating correlation coefficients in a series of papers. The first of these papers was *Correlated Averages*. Edgeworth, an economist who appears to be a self-taught mathematician, was someone who Pearson said that the biometricians might claim as one of their own. As early as 1885, Edgeworth was working on calculations related to **analysis of variance**. But, as so often was the case, Pearson fell out with his ingenious and knowledgeable statistical colleague and denied that Edgeworth’s work had influenced him.

In modern notation, the product-moment formula is $r = \sum xy / \sqrt{\sum x^2 \sum y^2}$.

This formula is based on x and y , the deviations of the measurements from the means of the two sets of measurements. In precomputer days, it was the formula of choice, and Pearson [3] noted that the formula ‘presents no practical difficulty in calculation, and therefore we shall adopt it.’ A further requirement of this correlational procedure is that the variables that are put into the exercise are *linearly* related. That is to say that when graphs of the pairs of variables are examined they are best shown as a straight line. A model is produced that is termed the general **linear model**, which may be depicted thus, $Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \dots + \beta_n X_n + e$. The independent variables are chosen and/or manipulated by the investigator, Y is the dependent variable and e is random error. The model is often termed a *probabilistic* model because it is based on a sample drawn randomly from the population. The coefficient of multiple correlation may be calculated from the separate simple relationships.

For the situation where we have two independent variables,

$$R^2_{Y.XZ} = \frac{r^2_{YX} + r^2_{YZ} - 2r_{YX}r_{YZ}r_{XZ}}{1 - r^2_{XZ}} \quad (1)$$

where the r s are the simple correlations of the labelled variables. Essentially, what we have here

2 History of Correlational Measurement

is a correlation coefficient that takes into account the correlation, the overlap between the independent variables.

This procedure is just one of the techniques used in *univariate statistical analysis*.

It must be appreciated that the model is applicable to cases where the fundamental question is, ‘what goes with what?’ – the correlational study, and ‘How is the dependent variable changed by the independent variables that have been chosen or manipulated?’ – the formal experiment. Some workers have been known to reject the correlational study largely because the differences in the dependent variable are, in general, individual differences or ‘errors.’ The true experiment attempts to reduce error so that the effect of the independent variables is brought out. Moreover, the independent variables in the correlational study are most often, but not always, continuous variables, whereas these variables in, for example, the analysis of variance are more likely to be categorical. The unnecessary disputes arise from the historical investigation of variate and categorical data and do not reflect the mathematical bases of the applications.

Among the earliest of studies that made use of the idea of correlational measurement in the fields of the biological and social sciences was the one carried out in 1877 by an American researcher, Henry Bowditch, who drew up correlation charts based on data from a large sample of Massachusetts school children. Although he did not have a method to compute measures of correlation, there is no doubt that he thought that one was necessary, as was an assessment of partial correlation. It was at this time that Sir **Francis Galton**, a founding father of statistical techniques, was in correspondence with Bowditch and who was himself working on the measurement of what he termed *correlation* and on the beginnings of regression analysis.

The **partial correlation** is the correlation of two variables when a third is held constant. For example, there is a correlation between height and weight in children, but the relationship is affected by the fact that age will influence the variables.

$$r_{12.3} = \frac{r_{12} - r_{13}r_{23}}{\sqrt{(1 - r_{13}^2)(1 - r_{23}^2)}} \quad (2)$$

and, for four variables a, b, c , and d , we find that $\frac{r_{ac}}{r_{ad}} = \frac{r_{bc}}{r_{bd}}$ and therefore $r_{ac} \cdot r_{bd} - r_{ad} \cdot r_{bc} = 0$. If there are two variables a and b and g is a constant, then

$r_{ab} = r_{ag} \cdot r_{bg}$, and, when a is set equal to b , the variance in a would be accounted for by g and this leads us to what are called the *communalities* in a correlation matrix. This approach leads us to Spearman’s *tetrad differences* and the beginnings of what he thought was a mathematical approach to his two-factor theory of intelligence and the development of the methods of **factor analysis**.

The general aim of using correlation to identify specific and general intelligences began to occupy a number of researchers, notably **Thurstone** and Kelley in the United States, and **Thomson** and **Burt** in Britain. The ongoing problem for many researchers was the subjective element in the methods. The fact that they did not produce determinate results reflected an argument that has not yet totally expired, ‘what goes into the analysis’ say the critics, ‘reflects what comes out.’ But increasing attention was given to developing methods that avoid subjective decisions. Apart from its beginnings in the study of intelligence and ability, factor analysis is used by a number of workers in the field of personality research in attempts to produce nonsubjective assessments of the existence of personality traits.

The growing use of factor analytic techniques produced a burgeoning of interest in the assessment of the *reliability* of tests. They were becoming increasingly sophisticated as researchers worried not only about their *validity* – and validity had been largely a matter of subjective face validity – but also of the respectability of their reliability. A leading scholar in this field was Cronbach who listed those aspects of test reliability that are of concern. They are test-retest reliability – is a test consistent over repeated administrations?; internal consistency – do the test items relate to the whole set of items?; alternate or parallel forms reliability – do equivalent forms of the test show high correlations? Cronbach himself offered a useful test, Cronbach’s α . A popular early test of reliability, the Kuder–Richardson estimate of reliability was developed to offset the difficulties of split-half methods, and the Spearman–Brown formula that compares the reliabilities of tests with their length. $r_{nn} = nr_{11}/1 + (n - 1)r_{11}$, where n is test length and r_{11} is the reliability of the test of unit length.

Galton’s view that ability, talent, and intellectual power are characteristics that are primarily innately determined – the *nature side* of the *nature-nurture* issue – sparked a series of investigations that examined the weights and the sizes of sweet pea seeds

over two generations. Later, he looked at human characteristics in a similar context, these latter data being collected by offering prizes for the submission of family records of physical endowments and from visitors to an anthropometric laboratory at the International Health Exhibition, held in 1884. He pondered on the data and noted (the occasion was when he was waiting for a train, which shows that his work was never far from his thoughts) that the frequency of adult children's measurements of height charted against those of the parents (he had devised a measure that incorporated the heights of both parents) produced a set of ellipses centred on the mean of all the measurements. This discovery provided Galton with a method of describing the relationship between parents and offspring using the regression slope.

An event of greatest importance led to the investigations that were to lie at the heart of the new science of biometrics. In his memoirs, [2] Galton noted that,

As these lines are being written, the circumstances under which I first clearly grasped the important generalisation that the laws of Heredity were solely concerned with deviations expressed in statistical units, are vividly recalled in my memory. It was in the grounds of Naworth Castle, where an invitation had been given to ramble freely. A temporary shower drove me to seek refuge in a reddish recess in the rock by the side of the pathway. There the idea flashed across me, and I forgot everything for a moment in my great delight. (p. 300).

An insight of the utmost utility shows us that if the characteristics of interest are measured on a scale that is based on its variability, then the regression coefficient could be applied to these data.

The formula is, of course, the mean of the products of what we now call z scores – the standard scores $r = \sum z_x z_y / n$.

It may be shown that the best estimate of the slope of the regression line is $b = r_{XY} s_Y / s_X$, where s is the sample standard deviation of Y and X , the two variables of interest.

The **multiple linear regression model** is given by $Y' = b_{YX.Z} X + b_{YZ.X} Z + a$, where Y' is termed the *dependent* or *criterion variable* and X and Z are the independent or predictor variables and a is a constant. The b 's are the constants that represent the weight given to the independent (predictor) variables in the estimation (prediction) of Y , the dependent variable. In other words, the regression model may be used to predict the value of a dependent variable from

a set of independent variables. When we have just one dependent and one independent variable, then the slope of the regression line is equivalent to r . For the values of b , we have constants that represent the weights given to the independent variables, and these are calculated on the basis of the partial regression coefficients.

The first use of the word correlation in a statistical context is by Galton in his 1888 paper, *Correlations and their measurement, chiefly from anthropometric data*. Pearson maintains that Galton had first approached the idea of correlation via the use of ranked data before he turned to the measurement of variates (see **Spearman's Rho**). The use of ranks in these kinds of data is usually attributed to **Charles Spearman**, who became the first Professor of Psychology at University College, London. He was, then, for a time a colleague of Pearson's in the same institution, but the two men disliked each other and were critical of each other's work so that a collaboration, that may have been valuable, was never entertained. A primary reason was that Pearson did not relish his approach to correlation that was central to his espousal of eugenics being sullied by methods that did not openly acknowledge the use of variates, essential to the law of ancestral heredity. It can, in fact, be rather easily shown that the modern formula for correlation using ranked data may be derived directly from the product-moment formula.

Spearman first offered the formula for the rank differences. $R = 1 - 3Sd/n^2 - 1$. Here, he uses S for the sum, rather than the modern version Σ and d is the difference in ranks. Later, the formula becomes $r_s = 1 - 6 \sum d^2 / n(n^2 - 1)$. An alternative measure of correlation using ranks was suggested by **Kendall**. This is his *tau* statistic (see **Kendall's Tau** – τ).

If two people are asked to rank the quality of service in four restaurants, the data may be presented thus:

Restaurant	a	b	c	d
Judge 1	3	4	2	1
Judge 2	3	1	4	2

Reordered

Restaurant	d	c	a	b
Judge 1	1	2	3	4
Judge 2	2	4	3	1

What is the degree of correspondence between the judges? We examine the data from Judge 2. Considering the rank of 2 and comparing it with the other ranks, 2 precedes 4, 2 precedes 3, but 2 does not precede 1. These outcomes produce the ‘scores’ +1, +1, and –1. When they are summed, we obtain +1. We proceed to examine each of the possible pairs of ranks and their totals. The maximum possible total obtained if there was perfect agreement between Judge 1 and Judge 2 would be 6. $\tau = (\text{actual total})/(\text{maximum possible total}) = -2/6 = -0.33$. This is a measure of agreement. This index is not identical with that of Spearman, but they both reflect association in the population.

George Udny Yule initially trained as an engineer, but turned to statistics when Pearson offered him a post at University College, London. Although, at first, the two maintained a friendly relationship, this soured when Yule’s own work did not meet with Pearson’s favor. In particular, Yule’s development of a coefficient of association in 2×2 contingency tables created disagreement and bitter controversy between the two men. In general, $X^2 = \sum (f_o - f_e)^2 / f_e$, where f_o is the observed, and f_e the expected, frequency of the observations. In a 2×2 table, this becomes

$$X^2 = (f_o - f_e)^2 \sum \frac{1}{f_e}. \quad (3)$$

When two variables, X and Y , have been reduced to two categories, it is possible to compute the **tetrachoric correlation coefficient**. This measure demands normality of distribution of the continuous variables and a linear relationship. The basic calculation is difficult and approximations to the formula are available. The procedure was just one of a number of methods provided by Pearson, but it lacks reliability and is rarely used nowadays.

The contingency coefficient is also an association method for two sets of attributes (see **Measures of Association**). However, it makes no assumptions

about an underlying continuity in the data and is most suitable for nominal variables. The technique is usually associated with Yule, and this, together with Pearson’s insistence that the variables should be continuous and normally distributed, almost certainly contributed toward the Pearson–Yule disputes.

The correlation technique of Spearman [4] is well known, but his legacy must be his early work on what is now called *factor analysis*. Factor analyses applied to matrices of intercorrelations among observed score variables are techniques that psychology can call its own for they were developed in that discipline, particularly in the context of the measurement of ability.

All the developments discussed here have led us to modern approaches of increasing sophistication. But these approaches have not supplanted the early methods, and correlational techniques produced in the nineteenth century and the later approaches to regression analysis will be popular in the behavioral sciences for a good while yet.

History of Discrimination and Clustering

There are two types of problems in classification. In problems of the first type, which are addressed using **discriminant analysis**, we are given the existence of two or more groups and using a sample of individuals from each, the object is to develop a rule under which an individual whose group membership is unknown can be assigned to the correct group. On the other hand, in problems of the second type, which are addressed using cluster analysis (*see* **Cluster Analysis: Overview**), the groups themselves are unknown *a priori* and must be determined by the data so that members within the same group are more similar than those that belong to different groups.

Although discriminant analysis and cluster analysis are distinct procedures, they address complementary classification problems, and thus, are often used together. Such is the case in numerical taxonomy. In numerical taxonomy, the entities to be classified are different animals, and observations on how different animals differ in their characteristics establish a notion of similarity (or dissimilarity) between them. The characteristics chosen by taxonomists vary from morphological attributes (e.g., weight), genetic (e.g., the number of chromosome pairs) to ecological and geographical data describing the habitat of animals. Animals are ‘close’ if their respective mean values on the selected characteristics are similar. Cluster analysis is useful in dealing with the multivariate data required to identify categories of similar animals. In taxonomy, the categories identified by cluster analysis are thought to correspond to natural taxa in the environment, the taxa that comprise the familiar seven-level hierarchy of kingdoms, phyla, classes, orders, families, genera, and species. Once the taxonomic groups have been identified, discriminant analysis can then be used to place an animal into the correct group within each level of the hierarchy.

Nonetheless, historically, discriminant analysis and cluster analysis have been developed independently. Initially, the problems addressed by discriminant analysis were different from what they are today. In the early work on what was then referred to as ‘discriminatory analysis’, classification problems did not involve assigning cases to known groups with

the least amount of error; rather, they involved confirming the distinctiveness of two or more known groups by testing the equality of their distributions [3]. For this reason, statistics for testing the equality of the distributions played an important role, as exemplified by **Pearson’s** ‘coefficient of racial likeness’ [7]. Problems in numerical taxonomy initiated the development of discriminant analysis in its contemporary form, a development undertaken principally by **Fisher** [4]. Fisher was concerned with the univariate classification of observations into one of two groups. For this problem, he suggested a rule that classifies the observation x into the i th population if $|x - \bar{x}_i|$ is the smaller of $|x - \bar{x}_1|$ and $|x - \bar{x}_2|$. For a p -variable observation vector ($p > 1$), Fisher reduced the problem to the univariate one by considering an ‘optimum’ linear combination, called the *discriminant function of the p -variables*. The criterion for defining a discriminant function was to maximize the ratio between the difference in the sample means and the pooled within-groups variance.

Following Fisher, the probabilistic approaches of Welch [16], von Mises [14], and Rao [8] predominated. Summarizing briefly, Welch derived the forms of Bayes rules and the minimax Bayes rule when the groups’ distributions were multivariate normal (*see* **Catalogue of Probability Density Functions**) and their covariance matrices were equal; von Mises specified a rule which maximized the probability of correct classification; and Rao suggested a distance measure between observations and groups, whose minimum value maximized the probability of correctly assigning observations to groups. Rao’s generalized distance measure built upon Pearson’s coefficient of racial likeness and **Mahalanobis**’ [6]. Wald [15] took a decision theoretic approach to discriminant analysis. Lately, nonparametric approaches to discriminant analysis have been a popular area of development [5]. In addition, of historical interest is a recent review [9] of the largely unknown but substantial and important work on discriminant analysis in the former Soviet Union that was initiated by Kolmogorov and his colleagues at Moscow University.

Early forms of cluster analysis included Zubin’s [17] method for sorting a correlation matrix that would yield clusters, and Stephenson’s [11] use of inverted (‘Q’) **factor analysis** to find clusters of personality types (*see* **R & Q Analysis**). However, the first systematic work was performed by Tryon [12], who viewed cluster analysis (‘a poor man’s

factor analysis' according to Tryon) as an alternative to using **factor analysis** for classifying people into types. Most of the methods developed by Tryon were in fact variants of multiple factor analysis [13]. **Cattell** [1], who also emphasized the use of cluster analysis for classifying types of persons, discussed four clustering methods: (a) 'ramifying linkage', which was a variation on what is now termed *single linkage*, (b) a 'matrix diagonal method' which was a graphical procedure, (c) 'Tryon's method' which is related to what currently would be described as average linkage (see **Hierarchical Clustering**), and (d) the 'approximate delimitation method' which was Cattell's extension of the ramifying linkage method. Cattell et al. [2] presented an iterative extension of the ramifying linkage method in order to identify two general classes of types: 'homostats' and 'segregates.' A homostat is a group in which every member has a high degree of resemblance with every other member in the group. On the other hand, a segregate is a group in which each member resembles more members of that group than other groups.

Since the 1960s, interest in cluster analysis has increased considerably, and a large number of different methods for clustering have been proposed. The new interest in cluster analysis was primarily due to two sources: (a) the availability of high-speed computers, and (b) the advocacy of cluster analysis as a method of numerical taxonomy [10]. The introduction of high-speed computers permitted the development of sophisticated cluster analysis methods, methods nearly impossible to carry out by hand. Most of the methods available at the time when high-speed computers first became available required the computation and analysis of an $N \times N$ similarity matrix, where N refers to the number of observations to be clustered. For example, if a sample consisted of 100 observations, this would require the analysis of a 100×100 matrix, which would contain 4950 unique values, hardly an analysis to be undertaken without mechanical assistance.

Cluster analysis appears now to be in a stage of consolidation, in which synthesizing and popularizing currently available methods, rather than introducing new ones, are emphasized. Consolidation is important, if for no other reason than to remove existing discrepancies and ambiguities. For example, the same methods of cluster analysis are often confusingly called by different names. 'Single linkage' is the standard name for a method of hierarchical

agglomerative clustering, but it is also referred to pseudonymously as 'nearest neighbor method', the 'minimum method', the 'space contracting method', 'hierarchical analysis', 'elementary linkage analysis', and the 'connectedness method'.

History of Factor Analysis: A Psychological Perspective

In 1904, **Charles Spearman** published two related papers that have had an immense influence on psychology in general and psychometrics in particular. In the first, [23] he outlined the classical or true-score model of reliability, dividing test performance, and therefore the variance in test scores, into a portion that was due to the individual's 'true' level on the trait in question and a portion that was random error of measurement. This can be represented symbolically as

$$X_{ij} = T_i + e_{ij} \quad (1)$$

The observed score of individual i on variable X at occasion j (X_{ij}) is composed of the true score of individual i on X (T_i) plus the error made in the measurement of person i at time j (e_{ij}). If T_i is constant, variation in a person's performance on successive measurements is due to randomly fluctuating errors. This distinction has formed the cornerstone of classical measurement theory (see **Measurement: Overview**) and is still highly influential.

By applying (1) to the scores for a sample on N individuals and finding the variance, we can break the variance in the observed scores down into two components, the variance in true scores, and the variance of the errors of measurement.

$$\sigma_X^2 = \sigma_T^2 + \sigma_e^2 \quad (2)$$

The ratio of true-score variance to total variance yields the reliability coefficient, and the square root of the error variance is the standard error of measurement, which can be used to determine an interval of uncertainty for a predicted score.

In his second paper, Spearman [24] enunciated one of the most influential theories of human cognitive abilities of the twentieth century, his theory of general intelligence, and laid the foundations for the method of data analysis that has come to be known as **factor analysis**. In this paper, Spearman divided the score of a person on an observed variable into a portion that represented what that variable had in common with the other variables in the analysis, which he called g or general intelligence, and a

portion that was unique to the variable in question, which he called s or specific performance.

$$X_{ij} = g_i + s_{ij} \quad (3)$$

The score of individual i on variable j (X_{ij}) is composed of person i 's score on the general ability variable g (g_i) plus the individual's score on the specific part of X_j (s_{ij}). Applying the logic of (2) to a set of scores yields the conclusion that the variance of a variable can be decomposed into a portion that is due to the common factor and another portion that is due to the specific factor.

$$\sigma_X^2 = \sigma_g^2 + \sigma_s^2 \quad (4)$$

Because there were two sources, or factors, contributing to the variance of each variable, this theory came to be known as the *two-factor theory*.

Three years earlier **Karl Pearson** [20] had derived what he called the **principal component** of a set of variables to account for the largest amount of variance explainable by a single dimension of the set (later generalized by **Hotelling** [10] to provide the full set of principal components). Because this procedure was not associated with a psychological theory and was computationally demanding, it did not get much attention from psychologists at the time.

There is an important ontological difference between component analysis as conceived by Pearson and Hotelling and factor analysis as conceived by Spearman. Component analysis is properly viewed as a data-reduction procedure. It results in an orthogonal (uncorrelated) representation of the variable space, but implies nothing about constructs underlying the variables. Factor analysis, on the other hand, has been viewed from its inception as a method for uncovering meaningful causal constructs to account for the correlations between variables. Some writers, for example, Velicer and Jackson [38], have argued that the distinction is unnecessary, and in one sense they are right. One should get a similar description of the data from either approach. However, as we shall see, the common factor approach generally yields better results in terms of one important index of the quality of the solution, ability to reproduce the original data.

Spearman's initial proposal of a single general factor of cognitive ability sparked an immediate trans-Atlantic debate between Spearman and E. L. Thorndike [27], who argued that there were many

2 History of Factor Analysis: A Psychological Perspective

factors of ‘intellect’ (his preferred term; see [29] for a description of the debate). In the face of this criticism, Spearman was forced to develop an analytic method to support his claim that a single factor was sufficient to account for the correlations among a set of tests. He was able to show [8] that a sufficient condition for the existence of a single factor was that an equation of the form

$$r_{ab}r_{cd} - r_{ac}r_{bd} = 0 \quad (5)$$

be satisfied for all possible sets of four tests. This criterion, known as the tetrad difference equation, would not be exactly satisfied for all possible sets of four tests with real data, but it might be approximated.

Debate over the nature of intelligence continued as one side produced a set of data satisfying the tetrad criterion and the other side countered with one that did not. Then, in 1917, **Cyril Burt** [2] offered a method for extracting a factor from a matrix of correlations that approximated Pearson’s principal component, but at great computational savings. Because his method placed the first factor through the average or geometric center of the set of variables, it became known as the centroid method for extracting factors (determining the initial location of a factor is called *factor extraction*). The centroid method was computationally straightforward and yielded useful factors. In the hands of **L. L. Thurstone**, it would become the standard method of factor extraction until computers became widely available in the late 1950s.

Although Spearman continued to offer his tetrad criterion as providing evidence of a single general factor of intelligence [25], the two-factor theory was dealt a serious blow in 1928 by Truman Kelley [17]. Using the method of partial correlation to remove g from the matrix of correlations among a set of ability variables, Kelley showed that additional meaningful factors could be found in the matrix of residual correlations. He argued that the distribution of residual correlations after extracting g could be used to test (and reject) the hypothesis of a single general factor and that an important goal for psychological measurement should be to construct tests that were pure measures of the multiple factors that he had found. Somewhat earlier, Thompson [26] had proposed a sampling approach to the conceptualization of factors that resulted logically in a hierarchy of factors depending on the breadth of the sampling. The concept of a hierarchy was later explicitly developed by

Vernon [39] and Humphreys [11] into general theories about the organization of human abilities.

Enter **L. L. Thurstone**, the most important single contributor to the development of factor analysis after Spearman himself. In 1931, Thurstone [30] published an important insight. He recognized that satisfying the tetrad criterion for any set of four variables was equivalent to saying that the rank of the 4×4 correlation matrix was 1. (We can roughly define the rank of a matrix as the number of independent dimensions it represents. More formal definitions require a knowledge of matrix algebra.) In this important paper, Thurstone argued that the rank of a matrix is the equivalent of the number of factors required to account for the correlations. Unless the rank of a matrix was 1, it would require more than one factor to reproduce the correlations (see below). He also showed how the centroid method could be used to extract successive factors much more simply and satisfactorily than Kelley’s partial correlation procedure.

Through the remainder of the 1930s, Thurstone continued to expand his conception of common factor analysis. He undertook a massive study of mental abilities, known as the Primary Mental Abilities study, in which 240 college-student volunteers took a 15-hour battery of 56 tests [31–34]. From analysis of this battery, he identified as many as 12 factors, seven of which were sufficiently well defined to be named as *scientific constructs of ability*. In addition, he developed the geometric interpretation of factors as the axes of a multidimensional space defined by the variables. This insight allowed him to recognize that the location of any factor is arbitrary. Once the multidimensional space (whose dimensionality is defined by the rank of the correlation matrix) is defined by the variables, centroid factors or principal components are used to define the nonzero axes of the space by satisfying certain conditions (see below), but these initial factors seldom seemed meaningful. Thurstone argued that one could (and should) move the axes to new positions that had the greatest psychological meaning. This process was called *factor rotation* (see **Factor Analysis: Exploratory**).

In his original work, Thurstone rotated the factors rigidly, maintaining their orthogonal or uncorrelated character. By 1938, he was advocating allowing the factors to become correlated or oblique. Geometrically, this means allowing the factors to assume

positions at other than 90 degrees to each other. Others, such as Vernon [39] and Humphreys [11] would later apply factor analysis to the matrices of correlations among the ‘first-order factors’ to obtain their hierarchical models.

Thurstone’s insights created three significant problems. First, the actual rank of any proper correlation matrix would always be equal to the number of variables because the diagonal entries in the matrix included not only common variance (the *g*-related variance of Spearman’s two-factor model) but also the specific variance. Thurstone suggested that the correlation matrix to be explained by the factors should not be the original matrix but one in which an estimate of the common variance of each variable had been placed in the appropriate location in the diagonal. This left investigators with the problem of how to estimate the common variance (or communality, as it came to be known).

The problem of estimating the communality was intimately related to the problem of how many factors were needed to account for the correlations. More factors would always result in higher communalities. In an era of hand computation, one did not want to extract factors more than once, so good communality estimates and a correct decision on the number of factors were crucial. Thurstone himself tended to favor using the largest correlation that a variable had with any other variable in the matrix as an estimate of the communality. Roff [22] argued that the squared multiple correlation of each variable with the other variables in the matrix provided the best estimate of the communality, and this is a starting point commonly used today. Others suggested an estimate of the reliability of each variable provided the best communality estimate.

The third problem resulted from the practice of rotation. The criteria for factor extraction provided a defined solution for the factors, but once rotation was introduced, there were an infinite number of equally acceptable answers. Thurstone attempted to solve this problem with the introduction of the concept of simple structure. In its most rudimentary form, the principle of simple structure says that each observed variable should be composed of the smallest possible number of factors, ideally one. In his most comprehensive statement on factor analysis, Thurstone [35, p. 335] offered five criteria that a pattern of factor loadings should meet to qualify as satisfying the simple structure principle, but most

attention has been directed to finding a rotation that produces a small number of nonzero loadings for any variable.

There are two primary arguments in favor of factor patterns that satisfy simple structure. First, they are likely to be the most interpretable and meaningful. A strong argument can be made that meaningfulness is really the most important property for the results of a factor analysis to have. Second, Thurstone argued that a real simple structure would be robust across samples and with respect to the exact selection of variables. He argued convincingly that one could hardly claim to have discovered a useful scientific construct unless it would reliably appear in data sets designed to reveal it.

Thurstone always did his rotations graphically by inspection of a plot of the variables and a pair of factors. However, this approach was criticized as lacking objectivity. With the advent of computers in the 1950s, several researchers offered objective rotation programs that optimized a numerical function of the factor loadings [e.g., 3, 19]. The most successful of these in terms of widespread usage has been the varimax criterion for rotation to an orthogonal simple structure proposed by Kaiser [14], although the direct oblimin procedure of Jennrich and Sampson [12] is also very popular as a way to obtain an oblique simple structure.

In addition to making analytic rotation possible, the rise of computers also sounded the death knell for centroid extraction. By the late 1960s the Pearson–Hotelling method of principal axis factor extraction had replaced all others. Several alternatives had been offered for how to estimate the communalities, including maximum likelihood [13, 18], alpha [16] and minimum residuals [7], but all employed the same basic extraction strategy that is described below.

There was also progress on the number-of-factors question that can be traced to the availability of computers. Although Hotelling [10] and Bartlett [1] had provided tests of the statistical significance of principal components (Bartlett’s sphericity test is still an option in SPSS), neither was used until computers were available because they did not apply to centroid factors. Rippe [21] offered a general test for the number of factors in large samples, and Lawley [18] had provided the foundation of a significance test for use with maximum likelihood factors. Others,

notably Kaiser [15] and **Cattell** [4] offered nonstatistical rules of thumb for the number of principal components to retain for rotation. Kaiser's criterion held that only factors that have **eigenvalues** (see below) greater than 1.0 should be considered, and Cattell suggested that investigators examine the plot of the eigenvalues to determine where a 'scree' (random noise factors) began. Kaiser's criterion became so popular that it is the default in SPSS and some other computer programs, and many programs will output the plot of the eigenvalues as an option.

Statistical criteria for the number of factors were criticized as being highly sensitive to sample size. On the other hand, one person's scree is another person's substantive factor, and Kaiser's criterion, although objective, could result in keeping a factor with an eigenvalue of 1.0001 and dropping one at 0.999. To solve these problems, Horn [9] proposed that in a study with m variables, $m \times m$ matrices of correlations from random data be analyzed and only factors from the real data with eigenvalues larger than the paired eigenvalue from random data be kept. This approach has worked well in simulation studies, but has not seen widespread application. A method with similar logic by Velicer [36] based on average squared partial correlations has also shown promise but seen little application.

By the early 1970s, the development of common factor analysis was all but complete. That this is so can be inferred from the fact that there has not been a major book devoted to the subject since 1983 [5], while before that date several important treatments appeared every decade. This does not mean that the method has been abandoned. Far from it; unrestricted (exploratory) factor analysis remains one of the most popular data analytic methods. Rather, work has focused on technical issues such as rules for the number of factors to extract, how large samples need to be, and how many variables need to be included to represent each factor. Although many investigators have contributed to developments on these topics, Wayne Velicer and his associates have been among the most frequent and influential contributors [37].

Overview of Factor Analysis

There are two basic ways to conceptualize factor analysis, an algebraic approach and a graphic or geometric approach. In this section, we will review

each of these briefly. For a further description, see the entry on common factor analysis. A thorough description of both approaches can also be found in Harman [6] or Gorsuch [5].

Algebraic Approach

Spearman [24] and Thurstone [35] both considered factors to represent real latent causal variables that were responsible for individual differences in test scores. Individuals are viewed as having levels of ability or personality on whatever traits the factors represent. The task for factor analysis is to determine from the correlations among the variables how much each factor contributes to scores on each variable. We can therefore think of a series of regression equations with the factors as predictors and the observed variables as the criteria. If there are K factors and p observed variables, we will have p regression equations, each with the same K predictors, but the predictors will have different weights in each equation reflecting their individual contributions to that variable.

Suppose we have a set of six variables, three measures of verbal ability and three measures of quantitative ability. We might expect there to be two factors in such a set of data. Using a generalization of Spearman's two-factor equation, we could then think of the score of a person (call him i for Ishmael) on the first test (X_{1i}) as being composed of some part of Ishmael's score on factor 1 plus some part of his score on factor 2, plus a portion specific to this test. For convenience, we will put everything in standard score form.

$$Z_{X_{1i}} = \beta_{X_1 F_1} Z_{F_{1i}} + \beta_{X_1 F_2} Z_{F_{2i}} + U_{X_{1i}} \quad (6)$$

Ishmael's score on variable X_1 ($Z_{X_{1i}}$) is composed of the contribution factor 1 makes to variable X_1 ($\beta_{X_1 F_1}$) multiplied by Ishmael's score on factor 1 ($Z_{F_{1i}}$) plus the contribution factor 2 makes to X_1 ($\beta_{X_1 F_2}$) times Ishmael's score on factor 2 ($Z_{F_{2i}}$) plus the residual or unique part of the score, $U_{X_{1i}}$. U is whatever is not contributed by the common factors and is called *uniqueness*. We shall see shortly that uniqueness is composed of two additional parts. Likewise, Ishmael's scores on each of the other variables are composed of a contribution from each of the factors plus a unique part. For example,

$$Z_{X_{2i}} = \beta_{F_1 X_2} Z_{F_{1i}} + \beta_{F_2 X_2} Z_{F_{2i}} + U_{X_{2i}} \quad (7)$$

If we have scores on variable 1 for a set of people, we can use (6) to see that factor analysis decomposes the variance of these scores into contributions by each of the factors. That is, for each variable X_j we can develop an expression of the following form

$$\sigma_{X_j}^2 = \beta_{X_j F_1} \sigma_{F_1}^2 + \beta_{X_j F_2} \sigma_{F_2}^2 + \sigma_{U_j}^2 \quad (8)$$

The variance of each observed variable is a weighted combination of the factor variances plus a unique contribution due to that variable.

The betas are known as *factor pattern coefficients* or *factor loadings*. As is the case in multiple correlations generally, if the predictors (factor) are uncorrelated, the regression weights are equal to the predictor-criterion correlations. That is, for orthogonal factors, the pattern coefficients are also the correlations between the factors and the observed variables. In factor analysis, the correlations between the variables and the factors are called *factor structure coefficients*. One of the major arguments that has been made in favor of orthogonal rotations of the factors is that as long as the factors are orthogonal the equivalence between the pattern and structure coefficients is maintained, so interpretation of the results is simplified.

Let us consider an example like the one above. Table 1 contains hypothetical correlations among three verbal and three quantitative tests from the Stanford–Binet Fourth Edition [28]. The matrix was constructed to be similar to the results obtained with the actual instrument.

Applying principal axis factor analysis (see the entry on common factor analysis) to this matrix yields the factor matrix in Table 2. This matrix is fairly typical of results from factoring sets of ability variables. There is a large first factor with all positive loadings and a smaller second factor with about half positive and half negative loadings (called a *bipolar*

Table 1 Hypothetical correlations between six subtests of the Stanford–Binet, Fourth Edition

factor). The large first factor has often been equated with Spearman's g factor.

One interpretation of a correlation is that its square corresponds to the proportion of variance in one variable that is accounted for by the other variable. For orthogonal factors, this means that a squared factor loading is the proportion of the variable's variance contributed by that factor. Summed across all common factors, the result is the proportion of the variable's variance that is accounted for by the set of common factors (note that uniqueness is not included). This quantity is called the *common variance* of the variable or its *communality*. For the case of K factors,

$$\text{Communality of } X_1 = \sum_{j=1}^K \beta_{X_1 F_j}^2 = h_{X_1}^2 \quad (9)$$

The communality of each variable is given in the last column of Table 1. The symbol h^2 is often used for communality and represents a variance term.

The remainder of each variable's variance, $(1 - h^2)$, is the variance unique to that variable, its uniqueness (symbolized u^2 , also a variance term). The unique variance is composed of two parts, variance that is due to reliable individual differences that are not accounted for by the common factors and random errors of measurement. The first is called *specificity* (symbolized s^2) and the second is simply error (e^2). Thus, Spearman's two 1904 papers lead to the following way to view a person's score on a variable

$$Z_{X_j i} = \beta_{F_1 X_j} Z_{F_{1i}} + \beta_{F_2 X_j} Z_{F_{2i}} + s_{X_j i} + e_{X_j i} \quad (10)$$

and link common factor theory with measurement theory. If we once again think of the scores for N people on the set of variables, the variance of each

6 History of Factor Analysis: A Psychological Perspective

variable (we are still considering standard scores, so each variable's total variance is 1.0) can be viewed in three interlocking ways (each letter corresponds to a kind of variance derived from (10)).

$$\begin{array}{lll} \text{Factor theory} & 1.0 = h^2 + u^2 & u^2 = s^2 + e^2 \\ & 1.0 = h^2 + s^2 + e^2 & r^2 = h^2 + s^2 \\ \text{Measurement} & 1.0 = r^2 + e^2 & \\ \text{theory} & & \end{array}$$

The symbol r^2 is used to indicate the reliable variance in test scores.

We can also consider the factor loading as revealing the amount of a factor's variance that is contributed by each variable. Again taking the squared factor loadings, but this time summing down the column of each factor, we get the values at the bottom of Table 2. These values are often referred to, somewhat inappropriately, as eigenvalues. This term is really only appropriate in the case of principal components. In this example, we used squared multiple correlations as initial communality estimates, so *factor variance* is the correct term to use. Note that the first factor accounts for over half of the variance of the set of six variables and the two factors combined account for about 2/3 of the variance.

Now, let us see what happens if we apply varimax rotation to these factors. What we would expect for a simple structure is for some of the loadings on the first factor to become small, while some of the loadings on the second factor become larger. The results are shown in Table 3. The first factor now has large loadings for the three verbal tests and modest loadings for the three quantitative tests and the reverse pattern is shown on the second factor. We would be inclined to call factor 1 a verbal ability factor and factor 2 a quantitative ability factor. Note

that the factors still account for the same amount of each variable's variance, but that variance has been redistributed between the factors. That is, the communalities are unchanged by rotation, but the factor variances are now more nearly equal.

There are two things about the varimax factor matrix that might cause us concern. First, the small loadings are not that small. The structure is not that simple. Second, there is no particular reason why we would or should expect the factors to be orthogonal in nature. We will allow the data to speak to us more clearly if we permit the factors to become correlated. If they remain orthogonal with the restriction of orthogonality relaxed, so be it, but we might not want to force this property on them. Table 4 contains the factor pattern matrix after rotation by direct oblimin.

There are two things to notice about these pattern coefficients. First, the large or primary coefficients display the same basic pattern and size as the coefficients in Table 3. Second, the secondary loadings are quite a lot smaller. This is the usual result of an oblique rotation. The other important statistic to note is that the factors in this solution are correlated 0.70. That is, according to these data, verbal ability and quantitative ability are quite highly correlated. This makes sense when we observe that the smallest correlation between a verbal test and a quantitative test in Table 1 is 0.33 and most are above 0.50. It is also what Spearman's theory would have predicted.

We can note one final feature of this analysis, which addresses the question of whether there is a difference between principal components analysis and common factor analysis. The factors provide a model for the original data and we can ask how well the model fits the data. We can reproduce the

original correlations, as accounted for by the factors, by multiplying the factor matrix by its transpose (most factor programs will give you this output if you ask for it). If the model fits well, the difference between the original correlations and the correlations as reproduced from the factor model should be similar (the difference is called the *residual*). Applying this test to the factors in Table 2, we find that all of the residuals with the correlations in Table 1 are less than .05, indicating quite good fit. If we had applied a principal components analysis to the same data, over half of the residual correlations would exceed .05, a much poorer fit. The lack of fit for principal components is a result of including unique variance in the correlation matrix; the reproduced correlations will be inflated.

Geometric Approach

The foundation of the geometric approach to factor analysis rests on the fact that variables can be represented by lines in space. The correlation between any pair of variables is directly related to the cosine of the angle between the lines representing the two variables; a right angle means $r = 0$, and a small angle means the correlation is large. Thus, highly correlated variables lie close to each other in space. Thurstone rotated factors by placing them close to clusters of variables in such a graphic display.

A proper correlation matrix will require as many dimensions as there are variables to completely represent the data. Our small six-variable example would require a six-dimensional space. However, we can make a plot showing the model of the data represented by any pair of factors by simply laying out the factors as axes of the space and plotting the variables as lines given by the factor loadings. The tip of each line is defined by the variable's factor loadings. Figure 1 contains the plot of the factor matrix from Table 2.

The variables form a fan-shaped array around the positive end of the first factor with the quantitative variables on the positive side of factor 2 and the verbal variables on the negative side of this factor. The factor matrix in Table 2 and the graphic display in Figure 1 give identical representations of the relations among the variables. The square of the length of the line representing each variable is equal to its communality. (From the Pythagorean theorem, $c^2 = a^2 + b^2$. The line representing a variable is c ,

Figure 1 Plot of the six variables and first two factors before rotation. Note that all loadings on the first factor are positive and the second factor is bipolar

Figure 2 Plot of the six variables and first two factors in which the factors have been rotated orthogonally 42 degrees clockwise

and a and b are the factor loadings, so this is the geometric equivalent of (9).)

Now consider the rotation concept. Factor 1 is a complex combination of all the variables while factor

2 contrasts verbal and quantitative tests. If we rotate the factors clockwise, factor 1 will come to represent the verbal tests more clearly and factor 2 will align with the quantitative ones. It looks like a rotation of about 45 degrees will do the trick.

When we apply the varimax rotation criterion, a rotation of 42 degrees produces an optimum solution. The plot of the rotated solution is shown in Figure 2. Notice that the variables stay in the same place and the factors rotate to new locations. Now, all of the variables project toward the positive ends of both factors, and this fact is reflected by the uniformly positive loadings in Table 3.

Figure 3 is a plot of the direct oblimin rotation from Table 4. Here we can see that the two factors have been placed near the centers of the two clusters of variables. The verbal cluster is a relatively pure representation of the verbal factor (1). None of the variables are far from the factor and all of their pattern coefficients on factor 2 are essentially zero. Equation building is a relatively pure measure of the quantitative factor, but two of the quantitative variables seem to also involve some elements of verbal behavior. We can account for this fact in the case of the Quantitative test because it is composed

in part of word problems that might involve a verbal component. The reason for the nonzero coefficient for Number Series is not clear from the test content.

The algebraic and graphical representations of the factors complement each other for factor interpretation because they provide two different ways to view exactly the same outcome. Either one allows us to formulate hypotheses about causal constructs that underlie and explain a set of observed variables. As Thurstone [35] pointed out many years ago, however, this is only a starting point. The scientific value of the constructs so discovered must be tested in additional studies to demonstrate both their stability with respect to the specific selection of variables and their generality across subject populations. Often they may be included in studies involving experimental manipulations to test whether they behave as predicted by theory.

History of Factor Analysis: A Statistical Perspective

Origins

Factor analysis is usually dated from **Charles Spearman's** paper '*General Intelligence' Objectively Determined and Measured* published in the *American Journal of Psychology* in 1904 [18]. However, like most innovations, traces of the idea can be found in earlier work by **Karl Pearson** [17] and others. All the same, it was a remarkable idea. Spearman, of course, did not invent factor analysis in the full glory of its later development. He actually proposed what would now be called a *one-factor* model though then it was, perversely, called a *two-factor model*. It arose in the context of the theory of correlation and partial correlation, which was one of the few topics in multivariate statistics that was reasonably well developed at that time. Technically speaking, it was not such a great step forward but it proved enough to unlock the door to a huge field of applications.

Spearman and most of his immediate followers were interested in measuring human abilities and, in particular, general intelligence. There was no interest in developing the general method of **multivariate analysis** which factor analysis later became. Factor analysis is unusual among multivariate statistical techniques in that it was developed almost entirely within the discipline of psychology. Its line of development was therefore subservient to the needs of psychological measurement of abilities in particular. This has had advantages and disadvantages. On the positive side, it has 'earthed' or grounded the subject, ensuring that it did not wander off into theoretical irrelevancies. Negatively, it had a distorting effect that emphasized some aspects and ignored others.

Returning to Spearman and the origins of factor analysis; the theory quickly grew. Sir **Cyril Burt**, see for example [5], was one of the first on the scene and, with his access to large amounts of data from the London County Council, was able to press ahead with practical applications.

The Key Idea

The key idea was that it might be possible to explain the correlations in sets of observable variables by the hypothesis that they all had some dependence on a common factor (or, later, factors). The fact that, in practice, the correlations were not wholly accounted for in this way was explained by the influence of other variables 'specific' to each observable variable. If this hypothesis were correct, then conditioning on the common variables (factors) should render the variables independent. In that sense, their correlations were 'explained' by the common factors. It was then but a short step to show that the variances of each variable could be partitioned into two parts, one arising from the common factor(s) and the other from the rest. The importance of each variable (its 'saturation' with the common factor) could be measured by its correlation with that factor – and this could be estimated from the observed correlations. In essence, this was achieved by Spearman in 1904.

In 1904, there was little statistical theory available to help Spearman but what there was proved to be enough. Correlation had been a major field of study. The invention of the product-moment correlation (see **Pearson Product Moment Correlation**) had been followed by expressions for **partial correlations**. A first-order partial correlation gives the correlation between a pair of variables when a third is fixed. Second-order coefficients deal with the case when two other variables are fixed, and so on. The expressions for the partial correlations presupposed that the relationships between the variables were linear. That was because product-moment correlation is a measure of linear correlation. Inspection of early editions of Yule's *Introduction to the Theory of Statistics* (starting with [21]) will show how prominent a place partial correlation occupied in the early days. Later, the emphasis shifted to multiple regression (see **Multiple Linear Regression**), which offered an alternative way of investigating the same phenomenon.

The result of Spearman's idea is that if the correlation between two variables is due to their common dependence on a third variable, then one can deduce that the form of the correlations has a particularly simple form. It is not entirely clear from the 1904 paper how Spearman went about this or what form of the relationship among the correlations

2 History of Factor Analysis: A Statistical Perspective

he actually used, but a simple way of arriving at his result is as follows.

Suppose we have a set of variables correlated among themselves. We suspect that these correlations are induced by their common dependence on a factor called G (Spearman used G in this context because he was using it to denote general intelligence). If that is the case, then conditioning on G should remove the correlation. Consider two variables i and j with correlation r_{ij} . If our hypothesis is correct, that correlation should vanish if we condition on G . That is, the partial correlation $r_{ij.G}$ should be zero (the ‘dot’ is used to denote ‘given’). Now,

$$r_{ij.G} = \frac{r_{ij} - r_{iG}r_{jG}}{\sqrt{1 - r_{iG}^2}\sqrt{1 - r_{jG}^2}}, \quad (1)$$

and so the necessary and sufficient condition for r to vanish is that

$$r_{ij} = r_{iG}r_{jG} \quad (i, j = 1, 2, \dots, p) \quad (i \neq j). \quad (2)$$

If we can find values r_{iG} ($i = 1, 2, \dots, p$) to satisfy these relations (approximately), then we shall have established that the mutual correlation among the variables can, indeed, be explained by their common dependence on the common factor G . This derivation shows that what came to be called *factor loadings* are, in fact, correlations of the manifest variables with the factor. As we shall see, this idea can easily be extended to cover additional factors but that was not part of Spearman’s original discovery.

The Statistical Strand

The first passing contact of statistics with the developing factor analysis was the publication of **Harold Hotelling’s** seminal paper [6] on **principal component analysis**. PCA is quite distinct from factor analysis but the distinction was, perhaps, less clear in the 1930s. Hotelling himself was critical of factor analysis, especially because of its lack of the statistical paraphernalia of inferential statistics.

Hotelling was followed, quite independently it seems, by Bartlett, [2–4], whose name is particularly remembered in this field for what are known as ‘Bartlett’ scores. These are ‘factor scores’ and we shall return to them below (see **Factor Score Estimation**). He also wrote more widely on the subject

and, through his influence, Whittle [20] made a brief excursion into the field.

There the matter appears to have rested until the immediate postwar period. By then, statistics, in a modern guise, was making great progress. **M. G. Kendall**, who was a great systematizer, turned his attention to factor analysis in [9] and also included it in taught courses at about the time and in one of his early monographs on multivariate analysis. This period also marks D. N. Lawley’s contribution concerned especially with fitting the factor model, see, for example, [10]. His one-time colleague, **A. E. Maxwell**, who collaborated in the writing of the book *Factor Analysis as a Statistical Method* [11], did practical factor analysis in connection with his work at the London Institute of Psychiatry. His expository paper [14], first read at a conference of the Royal Statistical Society in Durham and subsequently published in the *Journal Series A*, is an admirable summary of the state of play around 1961. In particular, it highlights the problems of implementing the methods of fitting the model that had already been developed – uncertain convergence being prominent among them.

However, factor analysis did not ‘catch on’ in a big way within the statistical community and there were a number of critical voices. These tended to focus on the alleged arbitrariness of the method that so often seemed to lead to an unduly subjective treatment. The range of rotations available, oblique as well as orthogonal, left the user with a bewildering array of ‘solutions’ one of which, surely, must show what the analyst desired. Much of this ‘unfriendly fire’ was occasioned by the fact that, in practice, factor analysts showed little interest in sampling error. It was easily possible to demonstrate the pitfalls by simulation studies on the basis of small sample sizes, where sampling error was often mistaken for arbitrariness. To many statisticians, the solidity of principal components analysis provided a surer foundation even if it was, basically, only a descriptive technique. However, to psychologists, ‘meaningfulness’ was at least as important a criterion in judging solutions as ‘statistical significance’.

The immediate postwar period, 1950–1960 say, marks an important watershed in the history of factor analysis, and of statistics in general. We shall come to this shortly, but it owed its origin to two important happenings of this period. One was the introduction of the electronic computer, which was, ultimately,

to revolutionize multivariate statistical analysis. The other was the central place given to probability models in the specification and analysis of statistical problems. In a real sense, statistics became a branch of applied probability in a way that it had not been earlier.

Prior to this watershed, the theory of factor analysis was largely about the numerical analysis of correlation (and related) matrices. In a sense, this might be called a *deterministic* or *mathematical* theory. This became such a deeply held orthodoxy that it still has a firm grip in some quarters. The so-called problem of factor scores, for example, is sometimes still spoken of as a ‘problem’ even though its problematic character evaporates once the problem is formulated in modern terms.

Next Steps

The first main extension was to introduce more than one common factor. It soon became apparent in applied work that the original one-factor hypothesis did not fit much of the data available. It was straightforward, in principle, to extend the theory, and Burt was among the pioneers, though it is doubtful whether his claim to have invented multifactor analysis can be substantiated (see [13]).

At about the same time, the methods were taken up across the Atlantic, most conspicuously by **L. L. Thurstone** [19]. He, too, claimed to have invented multifactor analysis and, for a time at least, his approach was seen as a rival to Spearman’s. Spearman’s work had led him to see a single underlying factor (G) as being common to, and the major determinant of, measures of human ability. Eventually, Spearman realized that this dominant factor could not wholly explain the correlations and that other ‘group’ factors had to be admitted. Nevertheless, he continued to believe that the one-factor model captured the essence of the situation.

Thurstone, on the other hand, emphasized that the evidence could be best explained by supposing that there were several (7 or 9) primary abilities and, moreover, that these were correlated among themselves. To demonstrate the latter fact, it was necessary to recognize that once one passed beyond one factor the solution was not unique. One could move from one solution to another by simple transformations, known as *rotations*, because that is how

they can be regarded when viewed geometrically. Once that fact was recognized, the question naturally arose as to whether some rotations were better or ‘more meaningful’ than others. Strong claims may be advanced for those having what Thurstone called ‘simple’ structure. In such a rotation, each factor depends only (or largely) on a subset of the observable variables. Such variables are sometimes called *group* variables, for obvious reasons.

Two Factors

The question of whether the correlation matrix can be explained by a single underlying factor therefore resolved itself into the question of whether it has the structure (2). If one factor failed to suffice, one could go on to ask whether two factors or more would do the job better. The essentials can be made clear if we first limit ourselves to the case of two factors.

Suppose, then, we introduce two factors G_1 and G_2 . We then require $r_{ij.G_1G_2}$ to be zero for all $i \neq j$. If G_1 and G_2 are uncorrelated, it turns out that

$$r_{ij} = r_{iG_1}r_{jG_1} + r_{iG_2}r_{jG_2} \quad (i \neq j) \quad (3)$$

$$= \lambda_{i1}\lambda_{j1} + \lambda_{i2}\lambda_{j2}, \text{ say.} \quad (4)$$

Pursuing this line of argument to incorporate further factors, we find, in the q -factor case, that

$$r_{ij} = \sum_{k=1}^q \lambda_{ik}\lambda_{jk} \quad (i \neq j). \quad (5)$$

In matrix notation,

$$\mathbf{R} = \mathbf{\Lambda}\mathbf{\Lambda}' + \mathbf{\Psi}, \quad (6)$$

where $\mathbf{\Lambda} = \{\lambda_{ik}\}$ and $\mathbf{\Psi}$ is a diagonal matrix whose elements are chosen to ensure that the diagonal elements of the matrix on the right add up to 1 and so match those of $\mathbf{R}$. The complements of the elements of $\mathbf{\Psi}$ are known as *the communalities* because they provide a measure of the variance attributable to the common factor.

The foregoing, of course, is not a complete account of the basis of factor analysis, even in its original form but it shows why the structure of the correlation matrix was the focal point. No question of a probability model arose and there was no discussion, for example, of standard errors of estimates. Essentially and originally, factor analysis

4 History of Factor Analysis: A Statistical Perspective

was the numerical analysis of a correlation matrix. This approach dominated the development of factor analysis before the Second World War and is still sometimes found today. For this reason, (6) was (and sometimes still is) spoken of as the factor analysis model.

The Model-based Approach

From about the 1950s onward, a fundamental change took place in statistics. This was the period when the ‘model’ became the point at which most statistical analysis began. A statistical model is a specification of the joint distribution of a set of random variables. Thus, if we have a set of variables $x_1, x_2, \dots, x_n$, a model will say something about their joint distribution.

Thus, Lawley and Maxwell’s *Factor Analysis as a Statistical Method* [11], which appeared in 1963, places what we would now call the normal linear factor model at the center. In factor analysis, there are three kinds of random variable. First, there are the manifest variables that we observe. We shall denote them by $x_1, x_2, \dots, x_p$ and make no distinction between random variables and the values they take. Then there are the factors, or **latent variables** denoted by $y_1, y_2, \dots, y_q$. The normal factor model supposes that

$$x_i \sim N\left(\mu_i + \sum_{j=1}^q \lambda_{ij} y_j, \Psi_i\right) \quad (i = 1, 2, \dots, p) \quad (7)$$

$$y_j \sim N(0, 1) \quad (j = 1, 2, \dots, q) \quad (8)$$

Or, equivalently,

$$x_i = \mu_i + \sum_{j=1}^q \lambda_{ij} y_j + e_i \quad (i = 1, 2, \dots, p), \quad (9)$$

where $e_i \sim N(0, \Psi_i)$ and where the e_i ’s are independent of the y_j ’s. The e ’s are the third kind of random variable referred to above. Their mutual independence expresses the conditional independence of the x ’s given the y ’s. The covariance matrix of the x_i ’s for this model is

$$\Sigma = \Lambda\Lambda' + \Psi, \quad (10)$$

which is of exactly the same form as (6) and so justifies us in regarding it as a stochastic version of the old (Spearman) ‘model’. The difference is that Σ is the covariance matrix rather than the correlation matrix. This is often glossed over by supposing that the x_i ’s have unit variance. This, of course, imposes a further constraint on Λ and Ψ by requiring that

$$\Psi_i + \sum_{j=1}^q \lambda_{ij}^2 = 1 \quad (i = 1, 2, \dots, p). \quad (11)$$

Viewed in a statistical perspective, we would now go on to fit the model, which amounts to finding estimates of Λ and Ψ to optimize some fitting function. The usual function chosen is the likelihood and the method is that of maximum likelihood (*see Maximum Likelihood Estimation*). In essence, the likelihood is a measure of the distance between Σ , as given by (10) and the sample covariance matrix. Other measures of distance, such as weighted or unweighted least squares, have also been used.

Prior to the 1950s, the problem of fitting the model was essentially that of finding Λ and Ψ in (10) to make it as close as possible to the sample covariance matrix without regard to the probabilistic interpretation.

When viewed in the statistical perspective, one can go on to construct tests of goodness-of-fit or calculate standard errors of estimates. That perspective also, as we shall see, provides a natural way of approaching other, related problems, which under the old approach were intractable, such as the so-called problem of *factor scores*.

Recent History of Factor Analysis

In the last few decades, factor analysis has developed in two different directions. One is in what is assumed about the factors and the other in what is assumed about the observable variables. In both cases, the scope of the basic factor model is enlarged.

What we have described so far is often known as *exploratory factor analysis*. Here, nothing is assumed *a priori* about the factor structure. The purpose of the analysis is simply to uncover whatever is there. Sometimes, on the other hand, there is prior information based either on previous empirical work or prior knowledge. For example, it may be known,

or suspected, that only the members of a given subset are indicators of a particular factor. This amounts to believing that certain factor loadings are zero. In cases like these, there is a prior hypothesis about the factor structure and we may then wish to test whether this is confirmed by a new data set.

This is called *confirmatory factor analysis* (see **Factor Analysis: Confirmatory**). Confirmatory factor analysis is a rather special case of a more general extension known as *linear structural relations modeling* or **structural equation modeling**. This originated with [7] and has developed enormously in the last 30 years. In general, it supposes that there are linear relationships among the latent variables. The object is then to not only determine how many factors are needed but to estimate the relationships between them. This is done, as in factor analysis, by comparing the observed covariance matrix with that predicted by the model and choosing the parameters of the latter to minimize the distance between them. For obvious reasons, this is often called *covariance structure analysis*.

Another ‘long-standing’ part of factor analysis can also be cast into the mold of linear structural relations modeling. This is what is known as *hierarchical factor analysis*, and it has been mainly used in intelligence testing. When factor analysis is carried out on several sets of test scores in intelligence testing, it is common to find that several factors are needed to account for the covariances – perhaps as many as 8 or 9. Often, the most meaningful solution will be obtained using an oblique rotation in which the resulting factors will themselves be correlated. It is then natural to enquire whether their covariances might be explained by factors at a deeper level, to which they are related. A second stage analysis would then be carried out to reveal this deeper factor structure. It might even be possible to carry the analysis further to successively deeper levels. In the past, hierarchical analysis has been carried out in an *ad hoc* way much as we have just described it. A more elegant way is to write the dependence between the first-level factors and the second level as linear relations to be determined. In this way, the whole factor structure can be estimated simultaneously.

The second kind of recent development has been to extend the range of observed variables that can be considered. Factor analysis was born in the context

of continuous variables for which correlations are the appropriate measure of association. It was possible, as we have seen, because the theory of partial correlation already existed. At the time, there was no such theory for categorical variables, whether ordered or not. This lopsided development reflected much that was going on elsewhere in statistics. Yet, in practice, categorical variables are very common, especially in the behavioral sciences, and are often mixed up with continuous variables. There is no good reason why this separation should persist. The logic of the problem does not depend, essentially, on the type of variable.

Extension to Variables of Other Types

Attempts to cope with this problem have been made in a piecemeal fashion, centering, to a large extent, on the work of Lazarsfeld, much of it conveniently set out in [12]. He introduced latent structure analysis to do for categorical – and especially binary variables – what factor analysis had done for continuous variables. Although he noted some similarities, he seemed more interested in the differences that concerned the computational rather than the conceptual aspects. What was needed was a broader framework within which a generalized form of factor analysis could be carried out regardless of the type of variable. Lazarsfeld’s work also pointed to a second generalization that was needed. This concerns the factors, or latent variables. In traditional factor analysis, the factors have been treated as continuous variables – usually normally distributed. There may be circumstances in which it would be more appropriate to treat the factors as categorical variables. This was done by Lazarsfeld with his latent class and latent profile models. It may have been partly because the formulae for models involving categorical variables look so different from those for continuous variables, that their essential unity was overlooked.

The key to providing a generalized factor analysis was found in the recognition that the exponential family of distributions provided a sufficient variety of forms to accommodate most kinds of observed variable. It includes the normal distribution, of course, but also the Bernoulli and multinomial distributions, to cover categorical data and many other forms as well that have not been much considered in latent variables analysis. A full development on these lines will be found in [1].

In this more general approach, the normal linear factor model is replaced by one in which the canonical parameter (rather than the mean) of the distribution is expressed as a linear function of the factors. Many features of the standard linear model carry over to this more general framework. Thus, one can fit the model by maximum likelihood, rotate factors, and so on. However, in one important respect it differs. It moves the focus away from correlations as the basic data about dependencies and toward the more fundamental conditional dependencies that the model is designed to express. It also resolves the disputes that have raged for many years about factor scores. A factor score is an ‘estimate’ or ‘prediction’ of the value of the factor corresponding to a set of values of the observed variables (*see Factor Score Estimation*). Such a value is not uniquely determined but, within the general framework, is a random variable. The factor score may then be taken as the expected value of the factor, given the data. It is curious that this has been the undisputed practice in **latent class analysis** from the beginning where allocation to classes has been based on posterior probabilities of class membership. Only recently is it becoming accepted that this is the obvious way to proceed in all cases.

Posterior probability analysis also shows that, in a broad class of cases, all the information about the latent variables is contained in a single statistic, which, in the usual statistical sense, is ‘sufficient’ for the factor. It is now possible to have a single program for fitting virtually any model in this wider class when the variables are of mixed type. One such is GENLAT due to Moustaki [15]. A general account of such models is given in [16].

Computation

Factor analysis is a computer-intensive technique. This fact made it difficult to implement before the coming of electronic computers. Various methods were devised for estimating the factor loadings and communalities for use with the limited facilities then available. The commonest of these, known as *the centroid method*, was based on geometrical ideas and it survived long enough to be noted in the first edition of Lawley and Maxwell [11]. Since then, almost all methods have involved minimizing the distance between the observed covariance (or correlation)

matrix $\mathbf{S}$ and its theoretical equivalent given by

$$\mathbf{\Sigma} = \mathbf{\Lambda}\mathbf{\Lambda}' + \mathbf{\Psi}. \quad (12)$$

These methods include least squares, weighted (or generalized) least squares, and maximum likelihood. The latter has been generally favored because it allows the calculation of standard errors and measures of goodness-of-fit. It is not immediately obvious that this involves a minimization of distance but this becomes apparent when we note that the log (likelihood) turns out to be

$$\begin{aligned} \log(\text{likelihood}) = \text{constant} + \frac{n}{2} \ln \det [\mathbf{\Sigma}^{-1}\mathbf{S}] \\ - \frac{n}{2} \text{trace}[\mathbf{\Sigma}^{-1}\mathbf{S}], \end{aligned} \quad (13)$$

where $\mathbf{\Sigma}$ is the covariance matrix according to the model and $\mathbf{S}$ is the sample covariance matrix. We note that $\mathbf{\Sigma}^{-1}\mathbf{S} = \mathbf{I}$ if $\mathbf{\Sigma} = \mathbf{S}$ and, otherwise, is positive. This means that, even if the distributional assumptions required by the model are not met, the maximum likelihood method will still be a reasonable fitting method. There are two principal approaches to minimizing (13). One, adopted by Jöreskog and Sörbom [8] uses the Fletcher–Powell (*see Optimization Methods*) algorithm. The second is based on the E-M algorithm. The latter has the conceptual advantage that it can be developed for the much wider class of models described in the section titled Extension to Variables of Other types.

The major software packages that are now available, also allow for various kinds of rotation, the calculation of factor scores, and many other details of the analysis.

In spite of the fact that the main computational problems of fitting have been solved, there are still complications inherent in the model itself. Most noteworthy are what are known as *Heywood cases*. These arise from the fact that the elements of the diagonal matrix $\mathbf{\Psi}$ are variances and must, therefore, be nonnegative. Viewed geometrically, we are looking for a point in the parameter space (of $\mathbf{\Lambda}$ and $\mathbf{\Psi}$) that maximizes the likelihood. It may then happen that the maximum is a boundary point at which one or more elements of $\mathbf{\Psi}$ is zero. The problem arises because such a boundary solution can, and often does, arise when the ‘true’ values of all the elements of $\mathbf{\Psi}$ are strictly positive. There is nothing inherently impossible about a zero value of a residual variance but they do seem practically implausible.

Heywood cases are an inconvenience but their occurrence emphasizes the inherent uncertainty in the estimation of the parameters. They are much more common with small sample sizes and the only ultimate ‘cure’ is to use very large samples.

What Then is Factor Analysis?

Factor analysis has appeared under so many guises in its 100-year history that one may legitimately ask whether it has retained that unitary character that would justify describing it as a single entity. Retrospectively, we can discern three, overlapping, phases that have coexisted. The prominence we give to each may depend, to some extent, on what vantage point we adopt – that of psychologist, statistician, or general social scientist.

At the beginning, and certainly in Spearman’s view, it was concerned with explaining the pattern in a correlation matrix. Why, in short, are the variables correlated in the way they are – it thus became a technique for explaining the pattern of correlation coefficients in terms of their dependence on underlying variables. It is true that the interpretation of those correlations depended on the linearity of relations between the variables but, in essence, it was the correlation coefficients that contained the relevant information. Obviously, the technique could only be used on variables for which correlation coefficients could be calculated or estimated.

The second approach is to write down a probability model for the observed (manifest) variables. Traditionally, these variables have been treated as continuous and it is then natural to express them as linear in the latent variables, or factors. In the standard normal linear factor model, the joint distribution of the manifest variables is multivariate normal and thus depends, essentially, on the covariance matrix of the data. We are thus led to the *covariance* rather than the *correlation* matrix as the basis for fitting. Formally, we have reached almost the same point as in the first approach though this is only because of the particular assumptions we have made. However, we can now go much further because of the distributional assumptions we have made. In particular, we can derive standard errors for the parameter estimates, devise goodness-of-fit tests, and so forth.

The third and final approach is to drop the specific assumptions about the kinds of variable and their

distributions. The focus then shifts to the essential question that has underlain factor analysis from the beginning. That is, is the interdependence among the manifest variables indicative of their dependence on a (small) number of factors (latent variables)? It is then seen as one tool among many for studying the dependence structure of a set of random variables. From that perspective, it is seen to have a much wider relevance than Spearman could ever have conceived.

History of Intelligence Measurement

The history of intelligence measurement can be roughly divided into three chronological periods: the first, a period of initial interest in defining intelligence and the establishment and use of intelligence tests; the second, a period of repudiation of the hereditarian assumptions underlying the tests; and the third, a period of resurgence of belief in the connection between intelligence and heredity. The first period lasted from about 1870 to the 1920s and is associated with **Francis Galton**, Alfred Binet, **Charles Spearman**, Robert Yerkes, and Lewis Terman. The second period, from the 1930s to the 1960s, is associated with the critics of intelligence testing such as Otto Klineberg and Horace Mann Bond. Finally, the period of resurgence began in 1969 with Arthur Jensen's controversial claims that intelligence is largely hereditary, claims repeated and enlarged upon by Richard Herrnstein and Charles Murray in their 1994 work, *The Bell Curve*.

Like his first cousin Charles Darwin, Francis Galton (1822–1911) substituted a belief in evolution and the power of heredity for religious orthodoxy. Like Darwin, he assumed that variation of traits in a population was key to understanding evolution and that most variation was hereditary. But rather than analyzing hereditary variation by seeking to understand its physiological cause, Galton chose to treat it statistically: by examining its distribution in a population. He noted that any given trait – height, say, or weight – was ‘normally’ distributed in a population, along a ‘bell curve’, with most individuals in the population displaying moderate height or weight, and fewer outliers at either extreme. But Galton did not stop at the measurement of physical traits: indeed, he believed it was even more important to measure mental traits, and these too he thought were normally distributed. In his 1869 work *Hereditary Genius: An Inquiry into Its Laws and Consequences*, Galton argued that genius, or talent, was inborn, that it tended to run in families, and that one's reputation was an accurate measure of one's inborn ability [5]. During the 1870s, Galton built up an arsenal of statistical concepts to treat heredity as a measurable relationship between generations. These concepts included **regression to**

the mean (in which certain characteristics revert to more typical values with each passing generation) and the coefficient of correlation (the degree to which one variable depends upon another). Galton's passion for measurement and belief in the power of heredity, combined with his concern for future social progress and fears about the decline of civilization, led him to advocate a program of ‘eugenics’ (a term he coined in 1883): a system of controlled mating in which those with desirable hereditary traits were encouraged to marry and produce offspring, while those deemed unfit were prevented from mating [9].

Charles Spearman (1863–1945), professor of psychology at University College, London, took up Galton's interest in using statistical tools to measure hereditary mental traits. Using the concept of the coefficient of correlation, Spearman determined that an individual's level of ability tends to hold steady in many different tasks, whether those be understanding a literary text or doing a mathematical calculation. The sameness of these abilities, the fact of their correlation, could be accounted for by their dependence on the individual's general intelligence – which Spearman identified as the ‘*g* factor’. General intelligence pervaded all of the individual's mental abilities and mental processes, was hereditarily determined, and held constant over an individual's lifetime. For Spearman, any given ability depended on two factors, the *g* factor and a special factor (*s*) that determined facility in a specific task. Spearman also believed that general intelligence was a real thing, an actual entity that exists in the brain, and for which a physiological correlate must ultimately be found [6]. While debates raged over the reification of intelligence, psychologists used Spearman's method of factor analysis, by which the variability of a trait can be reduced to one or more underlying factors or variables, to claim scientific status in the 1920s and 1930s [12]. Spearman's student **Cyril Burt** (1883–1971) broadened Spearman's use of factor analysis from intelligence and in his 1940 work *Factors of the Mind* applied it to analyzing emotion and personality [1].

In France, the psychologist Alfred Binet (1857–1911) developed an approach to understanding intelligence that was very different from Spearman's. The French government commissioned Binet in 1904 to produce a test of ability to identify sub-normal children in school classrooms, so that they

2 History of Intelligence Measurement

could be removed and given special education, allowing the other children to progress normally. Binet had previously been interested in the experimental study of the highest and most complex mental processes, and of individuals of high ability; with his colleague Theodore Simon (1873–1961), Binet determined what tasks a normal child, of a given age, could be expected to do, and then based his test on a series of 30 tasks of graded difficulty. Binet and Simon published their results in *L'annee Psychologique* in 1905, revising their test in 1908 and again in 1911. Though some identified the general capacity that such a test seemed to assess with Spearman's general factor of intelligence, Binet and Simon referred to the ability being tested as 'judgment'. They were, unlike Spearman, more interested in the description of individuals than in developing a theory of general intelligence, and their work did not have the strong hereditarian overtones that Spearman's did [6].

Binet and Simon's test for mental ability was refined and put to use by many other psychologists. In Germany, the psychologist William Stern argued in 1912 that the mental age of the child, as determined by the test, should be divided by the child's chronological age, and gave the number that resulted the name 'IQ' for intelligence quotient [9]. But it was in the United States that the Binet–Simon IQ test found its most receptive audience, and where it was put to the hereditarian ends that both Binet and Stern had renounced. The psychologist Henry Herbert Goddard (1866–1957), for example, used the test to classify patients at the New Jersey Training School for Feeble-minded Boys and Girls, a medical institution housing both children and adults diagnosed with mental, behavioral, and physical problems. Goddard subsequently developed, in part on the basis of his experience at the Training School, a theory that intelligence was unitary and was determined by a single genetic factor. He also used IQ tests on immigrants who came to America through the Ellis Island immigration port [13].

At Stanford University, the educational psychologist Lewis Terman (1877–1956) and his colleagues used IQ tests to determine the mental level of normal children, rather than to identify abnormal ones, an application that represented a significant departure from Binet's original intention. Terman called his elaboration of Binet's test the 'Stanford-Binet', and it became the predecessor and prototype

of the standardized, multiple-choice tests routinely taken by American students from the elementary grades through the college and postgraduate years [3]. But, psychologists moved the intelligence test beyond its application to performance in school. With the entrance of the United States into World War I in 1917, the comparative psychologist Robert M. Yerkes, supported by the National Research Council, proposed to the US Army a system of mass testing of recruits, which would determine whether they were fit for army service and, if so, what tasks best suited them [2]. Mass testing of thousands of soldiers differed greatly from Binet's individualist emphasis, but it raised psychology's public profile considerably: after the war, psychologists could justifiably call themselves experts in human management [4, 10]. Again, the results of the army testing were interpreted in hereditarian ways: psychologists argued that they showed that blacks and immigrants, especially from southern and eastern Europe, were less intelligent than native-born whites. Such arguments lent support to the call for immigration restriction, which passed into law in 1924.

Even as the IQ testers achieved these successes, they began to receive harsh criticism. Otto Klineberg (1899–1992), a psychologist trained under the anthropologist Franz Boas, made the best known and most influential attack. Klineberg argued that the supposedly neutral intelligence tests were actually compromised by cultural factors and that the level of education, experience, and upbringing so affected a child's score that it could not be interpreted as a marker of innate intelligence. Klineberg's work drew on that of lesser-known black psychologists, most notably Horace Mann Bond (1904–1972), an educator, sociologist, and university administrator. Bond showed that the scores of blacks from the northern states of New York, Ohio, and Pennsylvania were higher than those of southern whites, and explained the difference in terms of better access to education on the part of northern blacks. Such an argument flew in the face of innatist explanations. Nonetheless, despite his criticisms of hereditarian interpretations of the tests, Bond never condemned the tests outright and in fact used them in his work as a college administrator. Intelligence tests could, he argued, be used to remedy the subjectivity of individual teachers' judgments. If used properly – that is, for the diagnosis of learning problems –

and if interpreted in an environmentalist way, Bond believed that the tests could actually subvert bias. By the mid-1930s, Bond's evidence and arguments had severely damaged the hereditarian interpretation of IQ test results [11].

By 1930, too, several prominent psychologists had made public critiques or undergone well-publicized reversals on testing. E. G. Boring (1886–1968) expressed skepticism that intelligence tests actually measured intelligence. And Carl Brigham (1890–1943), who had in 1923 published a racist text on intelligence, recanted his views by the end of that decade [6].

The trend toward environmentalist and cultural critiques of intelligence testing met a strong opponent in Arthur Jensen, a psychologist at the University of California, Berkeley. In 1969, his controversial article 'How Much Can We Boost I.Q. and Scholastic Achievement' claimed that 'compensatory education has been tried and it apparently has failed' [8]. Jensen argued that it was in fact low IQ, not discrimination, cultural or social disadvantages, or racism that accounted for minority students' poor performance in intelligence tests and in school. His claim relied to an extent on Cyril Burt's twin studies, which purported to show that identical twins separated at birth and raised in different environments were highly similar in mental traits and that such similarity meant that intelligence was largely genetically determined. (In 1974, Leon J. Kamin investigated Burt's twin studies and concluded that Burt had fabricated his data.) Jensen's argument was in turn echoed by the Harvard psychologist Richard Herrnstein (1930–1994), who argued that because IQ was so highly heritable, one should expect a growing stratification of society based on intelligence and that this was in fact happening in late twentieth-century America. Expanded and developed, this same argument appeared in *The Bell Curve: Intelligence and Class Structure in American Life*, which Herrnstein published with the political scientist Charles Murray in 1994 [7]. Both in 1970 and 1994, Herrnstein's argument met a firestorm of criticism.

Attempts to define and measure intelligence are always tied to social and political issues, so the controversy that attends such attempts should come as

no surprise. Just as the post-World War I enthusiasm for IQ testing must be understood in the context of immigration restriction, Jensen's and Herrnstein's interest in intelligence and heredity arose against a background of debates over civil rights, affirmative action, and multiculturalism. From Galton's day to the present, IQ testers and their critics have been key players in the ongoing conversation about the current state and future direction of society.

History of Mathematical Learning Theory

For those psychologists with a sense of their discipline's past, the best known mathematical learning theorist has to be **Clark L. Hull** whose *Principles of Behavior* [10] and related works appeared to epitomize modern formal thinking in the behavioral sciences. Unfortunately, a closer look at the models and the modeling process shows Hull to be more of a nineteenth-century figure than one from the twentieth in that the models were fundamentally deterministic, and had been created by less than transparent or accepted mathematical means such as least squares. Consequently, this account of mathematical learning theory will not start or concern itself with Hull, but with a small but skillful group of psychologists and statisticians whose work was considerably more professional and more up-to-date than Hull's, and hence more worthy of the label 'modern'. These include **Robert R. Bush**, Frederick Mosteller, William K. Estes, and R. Duncan Luce. Between them, they created what quickly became known as Mathematical Learning Theory (MLT), although their ideas were rapidly taken up by workers in many other areas, thus subsuming MLT into the larger activity of an emerging *mathematical psychology* (see the three volumes of the *Handbook of Mathematical Psychology*, [14, 15], edited by Luce, Bush, and Galanter, for a detailed picture of the field's scope in the early 1960s).

What distinguished the approach of all four workers from the earlier efforts by Hull are their views about behavior: this was taken to be *intrinsically* uncertain and probabilistic. Early on, Estes made this explicit by referring to his brand of MLT as *statistical* learning theory, while Bush and Mosteller titled their seminal 1955 text *Stochastic Models for Learning* [5]. Hull, in comparison, had generated models which assumed that all behavior could be represented by a nonprobabilistic process, with any variation being bolted onto this essentially deterministic framework as error or 'behavioral oscillation' (to use Hull's phrase), in much the same way as a linear regression model (see **Multiple Linear Regression**) consists of fixed, unvarying components plus a random error variable. This nineteenth-century Newtonian worldview had long vanished in physics and related sciences under the onslaught of quantum theory, leaving

Hull (who was often claimed to be psychology's Isaac Newton) as a conceptually conservative figure in spite of the apparent novelty of, say, his use of modern symbolic logic in formalizing an axiomatic system for rote learning studies [11]. What the modern advocates of MLT did was to base all their modeling on the *probability* of action, with the clear assumption that this was the only way in which one could approach behavior. Many also drew on quantum theory formulations, in particular, **Markov chains**, which had originally been developed to model the probabilistic emission of particles from radioactive sources (see the writings of the MLT guru William Feller: for example, his 1957 textbook [8]). Thus, the conceptual basis of all flavors of these early versions of MLT was the probability of the event of interest, usually a response, or the internal processes that generated it, including the sampling and linking of stimulus and response elements by some probabilistic conditioning mechanism. (Notice that in the 1950s, conditioning, whether of the Pavlovian, Skinnerian, or Guthrieian variety, or mixtures of the three, tended to dominate empirical and theoretical work in learning.)

Although the honor of publishing the first paper embodying the new approach has to go to Estes in 1950, the most ambitious early programme into MLT was undoubtedly the one undertaken by Bush and Mosteller. This culminated in their 1955 textbook, which not only laid down a general system of considerable maturity and sophistication for modeling behavior, but also applied this to the detailed analysis of results culled from five areas of human and animal learning: imitation, avoidance learning, maze running, free recall verbal learning, and symmetric choice [5]. However, the claimed generality of this work, together with its lack of commitment to any particular theory of learning in that it attempted to embrace (and model) them all, meant that from the start there existed a certain distance or conceptual tension between Estes, on the one hand, and Bush and Mosteller, on the other. Thus, Estes had early on explicitly positioned his work within a Guthrieian setting by referring to it as 'Stimulus Sampling Theory' [7], while Bush and Mosteller commented that 'Throughout this book we have attempted to divorce our model from particular psychological theories' [4, p. 332].

This tension was somewhat increased by Bush and Mosteller's formal claim that Estes's stimulus sampling theory could be subsumed under their

2 History of Mathematical Learning Theory

system of *linear operators* (see their [5, Chapter 2]; also their initial comments that ‘a stimulus model is not necessary to the operator approach’, [5, p. 46]). What they were attempting was the development of a flexible mathematical system which could be tweaked to model many theoretical approaches in psychology by varying the range (and meaning) of allowable parameter values (but not model type) according to both the theory and the experimental domain. So ambitious a project was, however, almost impossible to carry out in practice, particularly as it also assumed a narrowly defined class of models, and was eminently mis-understandable by learning theorist and experimentalist alike. And so it proved. What now happened to MLT from the late 1950s was an increasing concentration on technical details and the fragmentation of the field as a result of strong creative disagreements, with infighting over model fit replacing Bush and Mosteller’s 1955 plea for a cumulative process of model development; tendencies, which, paradoxically, they did little to discourage. Indeed, their eight model comparison in [6] using the 1953 Solomon and Wynne shock avoidance data could be said to have kick-started the competitive phase of MLT, a direction hastened by the work of Bush, Galanter, and Luce in the same 1959 volume, which pitted Luce’s *beta* model for individual choice against the linear operator one, in part using the same Solomon and Wynne summary numbers [4].

Of course, comparing one model with another is a legitimate way of developing a field, but the real lack at the time of any deep or well-worked out theories of learning meant that success or failure in model-fitting was never unambiguous, with the contenders usually having to fall back on informal claims of how much closer their (*unprioritized* and *unprioritizable*) collective predictions were to the data than those of their opponents. This also made the issue of *formal* tests of goodness of fit, such as chi-square, problematic for many workers (see Bower’s careful but ultimately unsatisfactory trip around this issue in [9, pp. 375–376]). Furthermore, the epistemological deficit meant that MLT would sooner or later have to face up to the problem of *identifiability*, that is, how well do models need to be substantively and formally specified in order to *uniquely* and *unambiguously* represent a particular data set. Not to do so opened up the possibility of finding that MLT’s theories are typically

underdetermined by the data, to quote the standard postpositivist mantra. (Consult [13, especially Chapter 12], for a carefully drawn instance of how to handle some problems of identifiability in reaction time studies originally raised by Townsend in, for example, [16]; see also [12] for a case study in the history of factor analysis).

Meanwhile, and seemingly almost oblivious to this debate, Estes single-mindedly pursued his vision of MLT as Stimulus Sampling Theory (SST), which claimed to be closer than most versions of MLT to psychological theorizing. Increasingly, however, SST was viewed as a kind of *meta-theory* in that its major claim to fame was as a creative resource rather than its instantiation in a series of detailed and specific models. Thus, according to Atkinson et al. [1, p. 372], ‘Much as with any general heuristic device, stimulus sampling theory should not be thought of as provable or disprovable, right or wrong. Instead, we judge the theory by how useful it is in suggesting specific models that may explain and bring some degree of orderliness into the data’. Consequently, from the 1966 edition of their authoritative survey of learning theory onwards, Hilgard and Bower treated MLT as if it was SST, pointing to the approach’s ability to generate testable models in just about every field of learning, from all varieties of conditioning to concept identification and two person interactive games, via signal detection and recognition, and spontaneous recovery and forgetting. In fact, Bower, on pages 376 to 377 of his 1966 survey of MLT [9], lists over 25 distinctive areas of learning and related fields into which MLT, in the guise of SST, had infiltrated (see also [1], in which Atkinson et al. take the same line over SST’s status and success). By the time of the 1981 survey [3], Bower was happy to explicitly equate MLT with SST, and to impute genius to Estes himself (p. 252).

Finally, all these developments, together with the increasing power of the computer metaphor for the human cognitive system, also speeded up the recasting and repositioning of the use of mathematics in psychology. For instance, Atkinson moved away from a completely analytical and formal approach by mixing semiformal devices such as flow charts and box models (used to sketch in the large scale anatomy of such systems as human memory) with mathematical models of the process side, for example, the operation of the rehearsal buffer linking the short and long term memory stores (see [2]). Such

hybrid models or approaches allowed MLT to remain within, and contribute to, the mainstream of experimental psychology for which a more thoroughgoing mathematical modeling was a minority taste. Interestingly, a related point was also advanced by Bower in his survey of MLT [9], where a distinction was made between rigorous mathematical systems with only minimal contact with psychology (like the class of linear models proposed by Bush and Mosteller) and overall ones like SST, which claimed to represent well-understood psychological processes and results, but which made few, if any, specific predictions. Thus, on page 338 of [9], Bower separates *specific-quantitative* from *quasi-quantitative* approaches to MLT, but then opts for SST on the pragmatic grounds that it serves as a persuasive example of *both*.

History of Multivariate Analysis of Variance

Origins of Multivariate Analysis of Variance (MANOVA)

Building on the work of **Karl Pearson**, who derived the chi-square distribution in 1900, and of ‘Student’ **W.S. Gossett** who derived the t distribution in 1908, **Fisher** in 1923 introduced the **analysis of variance (ANOVA)** as a useful approach to studying population differences on a single ($p = 1$) dependent variable. The multivariate generalization of ANOVA – **multivariate analysis of variance (MANOVA)** – for studying population differences on $p > 1$ dependent variables soon followed. (NB Although Bartlett [2] and Roy [16–18] used variations of the term, the term ‘multivariate analysis of variance’, exactly written as such, is attributable to Roy [19].)

The MANOVA procedure was originally developed by Wilks [22] in 1932 on the basis of the generalized likelihood-ratio (LR), an application of Fisher’s **maximum likelihood** principle (*see Maximum Likelihood Estimation*). Fisher had introduced maximum likelihood in germinal form in 1912 [5] but did not provide a full development until 1922 [6]. The principle of maximum likelihood provides a statistical criterion for evaluating the consistency of a set of data with hypotheses concerning the data. Suppose we have N independent and identically distributed random variables denoted

$$\mathbf{Y} = [Y_1, Y_2, \dots, Y_N]' \quad (1)$$

in column vector notation, a corresponding column vector of observed data

$$\mathbf{y} = [y_1, y_2, \dots, y_N]' \quad (2)$$

drawn from $\mathbf{Y}$, and a joint probability density function (pdf) given by $f(\mathbf{y}; \Theta)$ with q unknown pdf parameters denoted as a column vector

$$\Theta = [\theta_1, \theta_2, \dots, \theta_q]' \quad (3)$$

The principle of maximum likelihood recommends that an estimate for Θ be found such that it maximizes the likelihood of observing those data that were

actually observed. In other words, given a sample of observations $\mathbf{y}$ for the random vector $\mathbf{Y}$, find the solution for Θ that maximizes the joint probability density function $f(\mathbf{y}; \Theta)$.

Importantly, the likelihood computed for a set of data is based on a hypothesis concerning that data: The likelihood will vary under different hypotheses. That hypothesis which produces the ‘maximum’ likelihood is the most consistent with the distribution of the data. By examining the ratio of likelihoods computed under two different hypotheses, we can determine which likelihood is more consistent with data. Suppose that the likelihood of the sample on H_0 is L_0 and that of H_1 is L_1 . The ratio L_0/L_1 gives us some measure of the ‘closeness’ of the two hypotheses. If they are identical the ratio is unity. As they diverge, the ratio diminishes to zero.

The LR provides a criterion by which we can compare the two hypotheses typically specified in MANOVA: (a) a null hypothesis H_0 that several k population centroids μ are equal ($\mu_1 = \mu_2 = \dots = \mu_k$.) and (b) a non-null hypothesis H_1 that at least two population centroids are not equal ($\mu_1 \neq \mu_2 \neq \dots \neq \mu_k$.) Lower ratios suggest less probable null hypotheses, conversely, higher ratios suggest more probable null hypotheses. The LR underlies the development of the test statistic Λ , Wilks’s Lambda, for comparing the means of several dependent variables between more than two groups. Arguably, it was not Fisher’s work that was most directly responsible for Wilks’s development of the generalized LR . While Fisher emphasized the use of the LR principle for parameter estimation, **Jerzy Neyman** and **Egon Pearson** focused on the hypothesis testing possibilities of the LR . These authors in a 1928 paper [12] used the LR for hypothesis testing that was restricted to comparing any number of k groups on a *single* dependent variable.

We briefly describe the derivation of Wilks’s Λ from the LR of two hypotheses; considerably greater detail can be found in [1]. In MANOVA, under the null hypothesis, we assume that a common multivariate normal probability density function (*see Catalogue of Probability Density Functions*) describes each group’s data.

Therefore, L_0 is

$$L_0 = \frac{e^{-\frac{1}{2}N}}{(2\pi)^{\frac{1}{2}Np}} \cdot \frac{1}{|S|^{\frac{1}{2}}}, \quad (4)$$

2 History of Multivariate Analysis of Variance

where S is the pooled within-groups covariance matrix. For L_1 , we need the likelihood of k separate multivariate normal distributions; in other words, each of the k multivariate normal distribution is described by a different mean and covariance structure. The likelihood for the non-null hypothesis, of group inequality, is

$$L_1 = \frac{e^{-\frac{1}{2}N}}{(2\pi)^{\frac{1}{2}Np}} \prod_{t=1}^k \frac{1}{|S_t|^{\frac{1}{2}n_t}}, \quad (5)$$

where n_t is the sample size of an individual group. Thus to test the hypothesis that the k samples are drawn from the same population as against the alternative that they come from different populations, we test the ratio L_0/L_1 :

$$\begin{aligned} LR = \frac{L_0}{L_1} &= \frac{\frac{e^{-\frac{1}{2}N}}{(2\pi)^{\frac{1}{2}Np}} \cdot \frac{1}{|S|^{\frac{1}{2}N}}}{\frac{e^{-\frac{1}{2}N}}{(2\pi)^{\frac{1}{2}Np}} \prod_{t=1}^k \frac{1}{|S_t|^{\frac{1}{2}n_t}}} \\ &= \frac{\prod_{t=1}^k |S_t|^{\frac{1}{2}n_t}}{|S|^{\frac{1}{2}N}} \\ &= \prod_{t=1}^k \left\{ \frac{|S_t|}{|S|} \right\}^{\frac{1}{2}n_t}. \end{aligned} \quad (6)$$

Further simplification of the LR is possible when we recognize that the numerator represents the between-groups variance and the denominator represents the total variance. Therefore, we have

$$LR = \prod_{t=1}^k \{ |S_t|/|S| \}^{\frac{1}{2}n_t} = \frac{|\mathbf{W}|}{|\mathbf{B} + \mathbf{W}|} = \frac{|\mathbf{W}|}{|\mathbf{T}|}, \quad (7)$$

where $|\mathbf{W}|$ is the determinant of the within-groups sum of squares (SS_{within}) and cross-products (CP_{within}) matrix, $|\mathbf{B} + \mathbf{W}|$ is the determinant of the sum of the between-groups sum of squares (SS_{between}) and cross-products (CP_{between}) matrix and the within-groups SS_{within} , CP_{within} matrix, and $|\mathbf{T}|$ is the determinant of the total sample sum of squares (SS_{total}) and cross-products (CP_{total}) matrix. The ratio $|\mathbf{W}|/|\mathbf{T}|$ is Wilks's Λ . Note that as $|\mathbf{T}|$ increases relative to $|\mathbf{W}|$ the ratio decreases in size with an

accompanying increase in the probability of rejecting H_0 .

Lambda is a family of three-parameter curves, with parameters based on the number of groups, the number of subjects, and the number of dependent variables, and is thus complex. Although Λ has been tabled for specific values of its parameters [7, 8, 10, 20], the utility of Λ depends on its transformation to either an exact or approximate χ^2 or F statistic. Bartlett [2] proposed an approximation to Λ in 1939 based on the chi-square distribution:

$$\chi^2 = -[(N-1) - 0.5(p+k)] \ln \Lambda, \quad (8)$$

which is evaluated at $p(k-1)$ degrees of freedom. Closer asymptotic approximations have been given by Box [4] and Anderson [1]. Transformations to exact chi-squared distributions have been given by Schatzoff [21], Lee [11], and Pillai and Gupta [14].

Rao [15] derived an F statistic in 1952 which provides better approximations to Λ cumulative probability densities compared to approximate chi-square statistics, especially when sample size is relatively small:

$$F = \left[\frac{1 - \Lambda^{1/s}}{\Lambda^{1/s}} \right] \left[\frac{ms - i(j-1)/2 + 1}{i(k-1)} \right], \quad (9)$$

where $m = N - 1 - (p+k)/2$, $s = \sqrt{[(p^2(k-1)^2 - 4/p^2 + (k-1)^2 - 5)]}$, and with $p(k-1)$, $ms - p(k-1)/2 + 1$ degrees of freedom.

In general, the LR principle provides several optimal properties for reasonably sized samples, and is convenient for hypotheses formulated in terms of multivariate normal parameters. In particular, the attractiveness of the LR presented by Wilks is that it yields test statistics that reduce to the familiar univariate F and t statistics when $p = 1$. If only one dependent variable is considered, $|\mathbf{W}| = SS_{\text{within}}$ and $|\mathbf{B} + \mathbf{W}| = SS_{\text{between}} + SS_{\text{within}}$. Hence, the value of Wilks's Λ is

$$\Lambda = \frac{SS_{\text{within}}}{SS_{\text{between}} + SS_{\text{within}}}. \quad (10)$$

Because the F ratio in a traditionally formulated as

$$F = \frac{SS_{\text{between}}}{SS_{\text{between}} + SS_{\text{within}}}, \quad (11)$$

Wilks's Λ can also be written as

$$\Lambda = \frac{1}{1 + \left[\frac{(k-1)}{(N-k)} \right] F}, \quad (12)$$

where N = the total sample size. This indicates that the relationship between Λ and F is somewhat inverse. The larger the F ratio is, the smaller the Wilks's Λ .

Most computational algorithms for Wilks's Λ take advantage of the fact that Λ can be expressed as a function of the **eigenvalues** of a matrix. Consider Wilks's Λ rewritten as

$$\Lambda = \frac{|\mathbf{W}|}{|\mathbf{B} + \mathbf{W}|} = \frac{1}{|\mathbf{B}\mathbf{W}^{-1} + \mathbf{I}|}. \quad (13)$$

Also consider for any matrix $\mathbf{X}$ there are λ_i eigenvalues, and for a matrix $(\mathbf{X} + \mathbf{I})$ there are $(\lambda_i + 1)$ eigenvalues. In addition, the product of the eigenvalues of a matrix is always equal to the determinant of the matrix (i.e., $\prod \lambda_i = |\mathbf{X}|$). Hence, $\prod (\lambda_i + 1) = |\mathbf{X} + \mathbf{I}|$. Based on this information, the value of Wilks's Λ can be written as the product of the eigenvalues of the matrix $\mathbf{B}\mathbf{W}^{-1}$:

$$\Lambda = \frac{1}{\prod (\lambda_i + 1)}. \quad (14)$$

MANOVA Example

We illustrate MANOVA using as an example one of its earliest applications [13]. In this study, there were five samples, each with 12 members, of aluminum diecastings ($k = 5$, $n_k = 12$, $N = 60$). On each specimen $p = 2$ measurements are taken: tensile strength

(TS , 1000 lb per square inch) and hardness (H , Rockwell's E). The data may be summarized as shown in Table 1.

We wish to test the multivariate null hypothesis of sample equality with the χ^2 approximation to Wilks's Λ . Recall that $\Lambda = |\mathbf{W}|/|\mathbf{B} + \mathbf{W}|$, so $\mathbf{W}$ and $\mathbf{B}$ are needed. First we calculate $\mathbf{W}$. Recognizing that each sample provides an estimate of $\mathbf{W}$, we use a pooled estimate of the within-sample variability for the two variables:

$$\begin{aligned} \mathbf{W} &= \mathbf{W}_1 + \mathbf{W}_2 + \mathbf{W}_3 + \mathbf{W}_4 + \mathbf{W}_5 \\ &= \begin{bmatrix} 78.95 & 214.18 \\ 214.18 & 1247.18 \end{bmatrix} + \begin{bmatrix} 223.70 & 657.62 \\ 657.62 & 2519.31 \end{bmatrix} \\ &\quad + \begin{bmatrix} 57.45 & 190.63 \\ 190.63 & 1241.78 \end{bmatrix} + \begin{bmatrix} 187.62 & 375.91 \\ 375.91 & 1473.44 \end{bmatrix} \\ &\quad + \begin{bmatrix} 88.46 & 259.18 \\ 259.18 & 1171.73 \end{bmatrix} \\ &= \begin{bmatrix} 636.17 & 1697.52 \\ 1697.52 & 7653.44 \end{bmatrix} \end{aligned} \quad (15)$$

The diagonal elements of $\mathbf{B}$ are defined as follows:

$$b_{ii} = \sum_{j=1}^k n_j (\bar{y}_{ij} - \bar{\bar{y}}_i)^2, \quad (16)$$

where n_j is the number of specimens in group j , $\bar{y}_{ij}$ is the mean for variable i in group j , and $\bar{\bar{y}}_i$ is the grand mean for variable i .

The off diagonal elements of $\mathbf{B}$ are defined as follows:

$$b_{mi} = b_{im} = \sum_{j=1}^k n_j (\bar{y}_{ij} - \bar{\bar{y}}_i)(\bar{y}_{mj} - \bar{\bar{y}}_m). \quad (17)$$

Table 1 Data from five samples of aluminum diecastings

Sample	TS		H		TS, H CP _{within}
	Mean	SS _{within}	Mean	SS _{within}	
1	33.40	78.95	68.49	1247.18	214.18
2	28.22	223.70	68.02	2519.31	657.62
3	30.31	57.45	66.57	1241.78	190.63
4	33.15	187.62	76.12	1473.44	375.91
5	34.27	88.46	69.92	1171.73	259.18
	$\bar{\bar{TS}} = 31.87$	$\sum SS_{w_{TS}} = 636.17$	$\bar{\bar{H}} = 69.82$	$\sum SS_{w_H} = 7653.44$	$\sum SS_{w_{TS,H}} = 1697.52$

4 History of Multivariate Analysis of Variance

Now we can find the elements of **B**:

$$\begin{aligned} b_{11} &= 12(33.40 - 31.87)^2 + 12(28.22 - 31.87)^2 \\ &\quad + 12(30.13 - 31.87)^2 + 12(33.15 - 31.87)^2 \\ &\quad + 12(34.27 - 31.87)^2 \\ &= 313.08 \end{aligned}$$

$$\begin{aligned} b_{22} &= 12(68.49 - 69.82)^2 + 12(68.02 - 69.82)^2 \\ &\quad + 12(66.57 - 69.82)^2 + 12(76.12 - 69.82)^2 \\ &\quad + 12(69.92 - 69.82)^2 \\ &= 663.24 \end{aligned}$$

$$\begin{aligned} b_{12} &= 12(33.40 - 31.87)(68.49 - 69.82) \\ &\quad + 12(28.22 - 31.87)(68.02 - 69.82) \\ &\quad + 12(30.13 - 31.87)(66.57 - 69.82) \\ &\quad + 12(33.15 - 31.87)(76.12 - 69.82) \\ &\quad + 12(34.27 - 31.87)(69.92 - 69.82) \\ &= 221.88 \end{aligned} \quad (18)$$

Therefore,

$$\mathbf{B} = \begin{bmatrix} 313.08 & 221.24 \\ 221.24 & 663.24 \end{bmatrix}. \quad (19)$$

Now we can obtain Wilks's Λ :

$$\begin{aligned} \Lambda &= \frac{|\mathbf{W}|}{|\mathbf{B} + \mathbf{W}|} \\ &= \frac{\begin{vmatrix} 636.17 & 1697.52 \\ 1697.52 & 7653.44 \end{vmatrix}}{\begin{vmatrix} 313.08 & 221.24 \\ 221.24 & 663.24 \end{vmatrix} + \begin{vmatrix} 636.17 & 1697.52 \\ 1697.52 & 7653.44 \end{vmatrix}} \\ &= \frac{1987314.77}{158700.04 + 1987314.77} = 0.93. \end{aligned} \quad (20)$$

Finally, we compute the chi-square approximation to Λ :

$$\chi^2 = -[(60 - 1) - 0.5(2 + 5)] \ln(0.93)$$

$$= -55.5(-0.07)$$

$$= 4.03, \text{ with } 2(5 - 1) = 8 \text{ df, } p = 0.85. \quad (21)$$

We conclude that the five samples have aluminum diecastings of equal tensile strength and hardness.

Wilks's Λ is the oldest and most widely used criterion for comparing groups, but several others have been proposed. Of these, the two most widely used are Hotelling's [9] trace condition and Roy's [20] largest-root criterion. Both of these are functions of the roots $\lambda_1, \lambda_2, \dots, \lambda_r$ of $\mathbf{BW}^{-1}$. Hotelling trace criterion is defined as

$$T = \sum_r \lambda_r, \quad (22)$$

and Roy's largest-root criterion is

$$\theta = \frac{(\lambda_{\max})}{(1 + \lambda_{\max})}. \quad (23)$$

Multivariate Analysis of Covariance (MANCOVA)

Just as ANOVA can be extended to the **analysis of covariance (ANCOVA)**, MANOVA can be extended to testing the equality of group means after their dependence on other variables has been removed by regression. In the multivariate analysis of covariance (MANCOVA), we eliminate the effects of one or more confounding variables (covariates) by regressing the set of dependent variables on them; group differences are then evaluated on the set of residualized means.

Bartlett [3] reported the first published example of a MANCOVA. The paper described an experiment to examine the effect of fertilizers on grain in which eight treatments were applied in each of eight blocks. On each plot of grain two observations were made, the yield of straw (x_1) and the yield of grain (x_2). The results obtained are shown in Table 2.

Differences among the eight blocks were of no interest and, therefore, variability due to blocks was

Table 2 Results from MANOVA examining the effect of fertilizer treatment on straw and grain yield

Source	df	SS_{x_1}	$CP_{x_1 x_2}$	SS_{x_2}
Blocks	7	86 045.8	56 073.6	75 841.5
Treatments	7	12 496.8	-6786.6	32 985.0
Residual	49	136 972.6	58 549.0	71 496.1
Total	63	235 515.2	107 836.0	180 322.6

Table 3 Results from MANCOVA examining the effect of fertilizer treatment on straw and grain yield

Source	df	SS_{x_1}	$CP_{x_1x_2}$	SS_{x_2}
Total	58	149 469.4	51 762.4	104 481.1

removed from the total variability, resulting in a new total (Table 3).

The multivariate null hypothesis of equality among the eight fertilizers was tested using Wilks's Λ :

$$\Lambda = \frac{|\mathbf{W}|}{|\mathbf{T}|} = \frac{\begin{vmatrix} 136972.6 & 58549.0 \\ 58549.0 & 71496.1 \end{vmatrix}}{\begin{vmatrix} 149469.4 & 51762.4 \\ 51762.4 & 104481.1 \end{vmatrix}} = \frac{7113660653}{7649097476} = 0.49. \quad (24)$$

Next the chi-square approximation to Λ was computed:

$$\begin{aligned} \chi^2 &= -[(56 - 1) - 0.5(2 + 8)] \ln(0.49) \\ &= -50.0(-0.31) \\ &= 15.5, \text{ with } 2(8 - 1) = 14 \text{ df, } p = 0.34. \end{aligned} \quad (25)$$

The conclusion was that the eight fertilizer treatments yielded equal amounts of straw and grain.

History of Path Analysis

History of Path Analysis and Structural Equation Modeling

At the end of the 19th Century British empiricism was the dominant philosophy in Great Britain, having been developed by such philosophers as John Locke (1632–1704), George Berkeley (1685–1753), David Hume (1711, 1776), James Mill (1773–1836) and his son, John Stuart Mill (1806–1873). **Karl Pearson** (1857–1936), trained as a physicist but renowned today as one of the founders of modern, multivariate statistics, with the chi-squared goodness of fit test, the Pearson product moment correlation coefficient, multiple correlation and regression, and with **G. U. Yule**, partial correlation as specific contributions, was also a highly influential empiricist philosopher of science. His *Grammar of Science* [25], published in a series of editions from 1892 to the 1930s popularized and amplified upon the empiricist philosophy of the Austrian physicist Ernst Mach, and was highly influential for a whole generation of scientists. Pearson held that concepts are not about an independent reality but rather are ‘ideal limits’ created by the mind in averaging experience. Scientific laws are but summaries of average results, curves fit to scattered data points, and useful fictions for dealing with experience [20], [22]. Pearson particularly thought of causation as but association through time and regarded statistical correlation as a way of measuring the degree of that association. Deterministic causation was merely one extreme, that of a perfect correlation. Zero correlation was a lack of association and absence of causation. Aware of a shift in physical thought from determinism to probabilistic theories, Pearson further thought of correlation as the proper way to represent probabilistic relationships in science. Pearson also echoed Mach’s skepticism about the reality of atoms and even questioned the new ideas in biology of the gene because these are not given directly in experience. This view was later reinforced by the views of the Austrian physicist, and founding member of the *Vienna Circle* of logical empiricists, Morris Schlick, who declared causality was an outmoded concept in modern physics, a relic of Newtonian determinism, which was giving way to a probabilistic quantum theory.

Pearson’s method of doing research was guided by his belief that this was to be done by forming associations from data. Correlations between variables and multiple correlation were ways of establishing associations between events in experience (*see* **Partial Correlation Coefficients; Multiple Linear Regression**). Pearson did not begin with substantive hypotheses and seek to test these, other than with the assumption that nothing was associated with anything unless shown to be so. So, tests of zero correlation, of independence, were the principal statistical tools, although he could test whether data conformed to a specific probability distribution or not. After he had demonstrated an association in a nonzero correlation, he would then seek to interpret this, but more in a descriptive manner, which summarized the results.

So it was in the face of this empiricist skeptical attitude toward causality that Sewell Wright [33], a young American agricultural geneticist, presented his new statistical methodology of path analysis for the study of causation in agriculture and genetics. He argued that computing correlations between variables does not represent the actual causal nature of the relationship between variables. Causes, he said, are unidirectional, whereas correlations do not represent direction of influence. On the other hand, he held that it was possible to understand correlations between variables in terms of causal relationships between the variables. He then introduced path diagrams to represent these causal relationships. He effectively developed the graphical conventions still used today: (observed) variables are represented by rectangles. Arrows between variables indicate unidirectional causal pathways between them. Curves with arrows at each end between variables indicate correlation between the variables. He envisaged chains of causes, and even considered the possibility of interactive and nonlinear relationships between variables. However, he confined path analysis, as he called his method, to linear causal relationships between variables, although this did not preclude nonlinear causal relationships in general. He then showed how correlations between variables could be shown to arise from common causes between variables. This led to the consideration of systems of correlated causes. Within such systems a variable that is the effect of two causal variables would be represented by an equation $X = M + N$.

2 History of Path Analysis

Then the variance of X would be given by the equation $\sigma_X^2 = \sigma_M^2 + \sigma_N^2 + 2\sigma_M\sigma_N r_{MN}$, where σ_X^2 is the variance of X , σ_M^2 is the variance of M , σ_N^2 the variance of N , σ_M and σ_N , the standard deviations of M and N , respectively, and r_{MN} the correlation between M and N . He then defined $\sigma_{X \cdot M}$ to be the standard deviation of X when all variables other than X and M are held constant. Holding N constant makes its variance and standard deviation go to zero. Hence the variance in X due to M alone is simply σ_M^2 . Hence $\sigma_{X \cdot M} = \sigma_M$ in this case. Next he defined the quantity $p_{X \cdot M} = \sigma_M / \sigma_X$. This is known as a ‘path coefficient’. From the fact, in this case that $\sigma_X^2 / \sigma_X^2 = \sigma_M^2 / \sigma_X^2 + \sigma_N^2 / \sigma_X^2 + (2 \times \sigma_M / \sigma_X \times \sigma_N / \sigma_X \times r_{MN})$, we may arrive at the total variance of X in standardized score form as $1 = p_{X \cdot M}^2 + p_{X \cdot N}^2 + 2p_{X \cdot M}p_{X \cdot N}r_{MN}$.

On the other hand, suppose we have two effect variables X and Y . Suppose, by way of a simplified representation of Wright’s exposition, there is an equation for each effect variable:

$$\begin{aligned} X &= p_{X \cdot M}M + e_X \\ Y &= p_{Y \cdot N}N + e_Y. \end{aligned} \quad (1)$$

These equations could be represented by the path diagram:

Further, suppose X, Y, M and N have unit variances and that we observe the correlations r_{XY} , r_{XM} , r_{XN} , r_{YM} , r_{YN} , and r_{MN} . From these equations and assuming e_X, e_Y are mutually uncorrelated and further each are uncorrelated with M , and N , then we can derive the following:

$$\begin{aligned} r_{XY} &= p_{X \cdot M}p_{Y \cdot N}r_{MN} \\ r_{XM} &= p_{X \cdot M} \end{aligned}$$

$$\begin{aligned} r_{XN} &= p_{X \cdot M}r_{MN} \\ r_{YM} &= p_{Y \cdot N}r_{MN} \\ r_{YN} &= p_{Y \cdot N}. \end{aligned} \quad (2)$$

Immediately we see that the parameters $p_{X \cdot M} = r_{XM}$ and $p_{Y \cdot N} = r_{YN}$ are given in terms of observable quantities. Since all other correlations are given in terms of these same parameters and the observed r_{MN} , we now have a way to test whether these equations represent the causal relationships between the variables by comparing them to the actual observed correlations. We see, for example, that $r_{XY} = r_{XM}r_{YN}r_{MN}$. If this is not so, then something is wrong with this representation of the causes of X and Y . Again, we should observe that $r_{XN} = r_{XM}r_{MN}$ and $r_{YM} = r_{YN}r_{MN}$. If none of these is the case, something is wrong with these equations as a causal model for these variables. Effectively, then, Wright saw that specifying a causal structure for the variables determined their intercorrelations, and further that the causal parameters of the structure could be estimated from the correlations among the variables. Finally, if certain correlations between the variables did not equal the values predicted by the equations and the parameter estimates, then this was evidence against the structure. So, his method of path analysis would allow one to test one’s prior knowledge or beliefs about the causal structure among the observed variables.

Consider another example involving a simple chain of causes.

The path diagram shows that B and N are uncorrelated. Furthermore, A is uncorrelated with B and M is uncorrelated with N . We will again assume that the variances of all variables are unity and have zero means. This gives rise to the equations for the effect variables:

$$\begin{aligned} X &= p_{X \cdot M}M + p_{X \cdot N}N \\ M &= p_{M \cdot A}A + p_{M \cdot B}B. \end{aligned} \quad (3)$$

Wright declared that in this case the effect of the more remote variable A on X was given by $p_{X \cdot A} = p_{M \cdot A}p_{X \cdot M}$, the product of the path coefficients along the path connecting A to X . We also can see how this model of the causes could be tested. From the two equations, we can further derive the hypothetical correlations among these variables as

$$\begin{aligned} r_{XM} &= p_{X \cdot M} & r_{AB} &= 0 \\ r_{AM} &= p_{M \cdot A} & r_{AN} &= 0 \\ r_{AX} &= p_{M \cdot A}p_{X \cdot M} & r_{MN} &= 0 \\ r_{BM} &= p_{M \cdot B} & r_{BN} &= 0 \\ r_{XN} &= p_{X \cdot N} & r_{BX} &= p_{M \cdot B}p_{X \cdot M} \end{aligned} \quad (4)$$

We see now that if this model holds, then $r_{AX} = r_{XM}r_{AM}$ must hold. This provides a test of the model when observed correlations are used. The variables B and N may also be unobserved error variables, and so the only observed correlations are between the variables A , M , and X . The remaining correlations are then given only by hypothesis.

Wright also showed remarkable prescience in considering the analysis of direct and indirect effects, of common causes, and common effects of several causes, and the effect of unmeasured ‘relevant’ causes of an effect variable that were also correlated with its other causes that were the focus of study.

When Wright’s article was published it was subsequently followed by a critical article by Niles [23] who quoted extensively Pearson’s *The Grammar of Science* (1900). According to Pearson, Niles held, correlation *is* causation. To contrast causation with correlation is unwarranted. There is no philosophical basis on which to extend to the concept of cause a wider meaning than partial or absolute association. Furthermore Niles could not see how you could study the causes of any specific variables, for, according to Pearson the causes of any part of the universe lead inevitably to the history of the universe as a whole. In addition there is, he held, no way to specify *a priori* the true system of causes among variables, that to do so implied that causation is a necessary connection between things and further that it is different from correlation. Furthermore even if a hypothesized system conforms to the observed correlations, this did not imply that it is the true system, for there could be infinitely many different equivalent systems created *a priori* to fit the same variables.

Wright responded with a rebuttal [34], arguing that his method was not a deduction of causes from correlations, but the other way around. Furthermore, he did not claim “that ‘finding the logical consequences’ of a hypothesis in regard to the causal relations depended on any prior assumption that the hypothesis is correct” (p. 241). If the hypothesized consequences do not conform to the observed correlations, then this allows us to regard the hypothesized system as untenable and in need of modification. If the hypothesized consequences correspond to independently obtained results, then this demonstrates the ‘truth’ of the hypothesis ‘in the only sense which can be ascribed to the truth of a natural law’ (p. 241). Niles followed with another attempted rebuttal (1923). But Wright went on to develop the method extensively in studying models of the heredity of traits as gene transfers between parents and offspring that manifest themselves in correlations between parents, offspring, and relatives [16, 35].

Path analysis at this point was not taken up by the behavioral or social sciences. Factor analysis at this point was a competing, well-established methodology for working with correlations, and was being used to study intelligence [29], [30] and personality. But even though it was a structural model, the exploratory factor analysis model then in use was applied in a manner that regarded all correlations as due just to common factors. But as all beginning statistics students are told, a correlation between two variables X and Y can be due to X being a cause of Y , Y being a cause of X , or there being a third variable Z that is a common cause of both X and Y . So, factor analysis only considers one of these as the causal structure for explaining all correlations. And in a purely exploratory mode it was used often by researchers without much prior consideration of what even the common causes might be. So, it was closer in research style to Pearson’s descriptive use of regression, where one automatically applied the model, and then described and summarized the results rather than as a model-testing method. But the path analysis models of Wright could consider each kind of causation in formulating causal models of correlations between variables, but these models were formulated prior to the analysis and the causal structures were given by hypothesis rather than summaries of results. The important thing was whether the pattern of correlations predicted by the model conformed to the observed pattern of correlations

among the variables. So, path analysis was a model-testing method.

Another reason that likely retarded the uptake of path analysis into the behavioral and social sciences at the outset was that this was a method used in genetic research, published in genetics and biological journals, so the technique was little known to researchers in the behavioral and social sciences for many years.

By a different route, the econometricians began implementing regression models and then extended these to a method mathematically equivalent to path analysis known as structural equation modelling. This was initially stimulated by such mathematical models of the economy as formulated by John Maynard Keynes [17], which used sets of simultaneous linear equations to specify relations between variables in the economy. The econometricians distinguished *exogenous variables* (inputs into a system of variables) from *endogenous variables* (variables that are dependent on other variables in the system). Econometricians also used matrix algebra to express their model equations. They sought further to solve several problems, such as determining the conditions under which the free parameters of their models would be identified, that is, determinable uniquely from the observed data [18]. They showed how the endogenous variables could ultimately be made to be just effects of the exogenous variables, given in the 'reduced equations'. They developed several new methods of parameter estimation such as two-stage [32] and three-stage least squares [36]. They developed both Full Information Maximum Likelihood (FIML) and Limited Information Maximum likelihood (LIML) estimates of unspecified parameters (*see Maximum Likelihood Estimation*). However, generally their models involved only measured observed variables.

Although in the 1950s logical empiricism reigned still as the dominant philosophy of science and continued to issue skeptical critiques of the idea of causation as an out-dated remnant of determinism, or to be replaced by a form of logical implication, several philosophers sought to restore causality as a central idea of science. Bunge [7] issued a significant book on causality. Simon [26] argued that causality is to be understood as a functional relation between variables, not a relation between individual events, like logical implication. This laid the groundwork for what followed in sociology and, later, psychology.

Blalock [3], a sociologist who had been originally trained in mathematics and physics, authored a highly influential book in sociology that drew upon the method of path analysis of Wright [35]. Blalock [4] also edited a collection of key articles in the study of causation in the social sciences, which was highly influential in the treatment of causality, its detection, and in providing research examples. A second edition [5] also provided newer material. This was also accompanied by a second volume [6] devoted to issues of detecting causation with experimental and panel designs. Duncan [8] wrote an influential introductory textbook on structural equation models for sociologists. Heise [10] also authored an important text on how to study causes with flowgraph analysis, a variant of path analysis.

A highly important development began in the latter half of the 1960s in psychology. Bock and Bargmann [2] described a new way of testing hypotheses about linear functional relations known as 'analysis of covariance structures'. This was followed up in the work of Karl Jöreskog, a Swedish mathematical statistician, who came to Educational Testing Service to work on problems of factor analysis. After solving the problem of finding a full information maximum likelihood estimation method for exploratory common factor analysis [12] (*see Factor Analysis: Exploratory*), Jöreskog turned his attention to solving a similar problem for confirmatory factor analysis [13] (*see Factor Analysis: Confirmatory*), which prior to that time had received little attention among factor analysts. This was followed by an even more general model that he called 'analysis of covariance structures' [14]. Collaboration with Arthur S. Goldberger led Karl Jöreskog to produce an algorithm for estimating parameters and testing the fit of a structural equation model with latent variables [15], which combined concepts from factor analysis with those of structural equations modeling. He was also able to provide for a distinction between free, fixed, and constrained parameters in his models. But of greatest importance for the diffusion of his methods was his making available computer programs for implementing the algorithms described in his papers. By showing that confirmatory factor analysis, analysis of covariance structures, and structural equation modeling could all be accomplished with a single computer program, this provided researchers with a general, highly flexible method for studying a great variety of

linear causal structures. He called this program 'LISREL' for 'linear structural relations'. It has gone through numerous revisions. But his program was shortly followed by others, which sought to simplify the representation of **structural equation models**, such as COSAN, [19], EQS [1] and several others (see **Structural Equation Modeling: Software**). Numerous texts, too many to mention here, followed, based on Jöreskog's breakthrough. A new journal, *Structural Equation Modeling* appeared in 1994.

The availability of easy-to-use computer programs for doing structural equation modeling in the 1980s and 1990s produced almost a paradigm shift in correlational psychological research from descriptive studies to testing causal models and renewed investigations of the concept of causality and the conditions under which it may be inferred. James, Mulaik, and Brett [11] sought to remind psychological researchers that structural equation modeling is not exploratory research, and that, in designing their studies, they needed to focus on establishing certain conditions that facilitated inferences of causation as opposed to spurious causes. Among these was the need to make a formal statement of the substantive theory underlying a model, to provide a theoretical rationale for causal hypotheses, to specify a causal order of variables, to establish self-contained systems of structural equations representing all relevant causes in the phenomenon, to specify boundaries such as the populations and environments to which the model applies, to establish that the phenomenon had reached an equilibrium condition when measurements were taken, to properly operationalize the variables in terms of conditions of measurement, to confirm empirically support for the functional equations in the model, and to confirm the model empirically in terms of its overall fit to data.

Mulaik [21] provided an amplified account first suggested by Simon in 1953 [28] of how one might generalize the concept of causation as a functional relation between variables to the probabilistic case. Simon had written "...we can replace the causal ordering of the variables in the deterministic model by the assumption that the realized values of certain variables at one point or period in time determines the probability distribution of certain variables at later points in time" [27, 1977, p. 54]. This allows one to join linear structural equation modeling with other, nonlinear forms of probabilistic causation, such as item-response theory.

Four philosophers of science [9] put forth a description of a method for discovering causal structure in correlations based on an artificial intelligence algorithm that implemented heuristic searches for certain zero partial correlations between variables and/or zero tetrad differences among correlations [29] that implied certain causal path structures. Their approach combined graph theory with artificial intelligence search algorithms and statistical tests of vanishing partial correlations and vanishing tetrad differences. They also produced a computer program for accomplishing these searches known as Tetrad. In a brief history of heuristic search in applied statistics, they argued that researchers had abandoned an optimal approach to testing causal theories and discovering causal structure first suggested by Spearman's (1904) use of tetrad difference tests, by turning to a less optimal approach in factor analysis. The key idea was that instead of estimating parameters and then checking the fit of the reproduced covariance matrix to the observed covariance matrix, and then, if the fit was poor, taking another factor with associated loadings to estimate, as in factor analysis, Spearman had identified constraints implied by a causal model on the elements of the covariance matrix, and sought to test these constraints directly. Generalizing from this, Glymour et al. [9] showed how one could search for those causal structures having the greatest number of constraints implying vanishing partial correlations and vanishing tetrad differences on the population covariance matrix for the variables that would be most consistent with the sample covariance matrix. The aim was to find a causal structure that would apply regardless of the values of the model parameters.

Spirtes, Glymour, and Scheines [31] followed the previous work with a book that went into considerable detail to show how probability could be connected with causal graphs. To do this, they considered that three conditions were needed for this: the Causal Markov Condition, the Causal Minimality Condition, and the Faithfulness Condition. Kinship metaphors were used to identify certain sets of variables. For example, the parents of a variable V would be all those variables that are immediate causes of the variable V represented by 'directed edges' of a graph leading from these variables to the variable in question. The descendants would be all those variables that are in directed paths from V . A directed acyclic

graph for a set of variables $\mathbf{V}$ and a probability distribution would be said to satisfy the Markov Condition if and only if for every variable W in $\mathbf{V}$, W is independent of all variables in $\mathbf{V}$ that are neither parents nor descendants of W conditional on the parents of W . Satisfying the Markov Condition allows one to specify conditional independence to occur between certain sets of variables that could be represented by vanishing partial correlations between the variables in question, conditional on their parents. This gives one way to perform tests on the causal structure without estimating model parameters. Spirtes, Glymour, and Scheines [31] showed how from these assumptions one could develop discovery algorithms for causally sufficient structures. Their book was full of research examples and advice on how to design empirical studies. A somewhat similar book by [24], because Spirtes, Glymour, and Scheines [31] drew upon many of Pearl's earlier works, attempted to restore the study of causation to a prominent place in scientific thought by laying out the conditions by which causal relations could be and not be established between variables. Both of these works differ in emphasizing tests of conditional independence implied by a causal structure rather than tests of fit of an estimated model to the data in evaluating the model.

History of Psychometrics

Introduction

Psychometrics can be described as the science of measuring psychological abilities, attributes, and characteristics. Such a ubiquitous and hybridized set of techniques has been said, not surprisingly, to have many protoscientific and professional antecedents, some dating back to antiquity. Modern psychometrics is embodied by standardized psychological tests. American psychometrician Lee Cronbach famously remarked in the 1960s, ‘the general mental test ... stands today as the most important single contribution of psychology to the practical guidance of human affairs’ [16, p. 113]. However, psychometrics has come to mean more than just the tests themselves; it also encompasses the mathematical, statistical, and professional protocols that underpin tests – how tests are constructed and used, and indeed, how they are evaluated.

Early Precedents

Historians have noted the examples of ‘mental testing’ in ancient China and other non-Western civilizations where forms of proficiency assessment were used to grade or place personnel. However, the most obvious template for psychometric assessment, with a more direct lineage to modern scientific manners, was the university and school examination. Universities in Europe first started giving formal oral assessments to students in the thirteenth century. With the invention of paper, the Jesuits introduced written examinations during the sixteenth century. In England, competitive university examinations began in Oxbridge institutions in the early 1800s [14]. By the end of the nineteenth century, compulsory forms of education had spread throughout much of the Western world. Greater social mobility and vocational streaming set the scene for practical forms of assessment as governments, schools, and businesses of industrialized nations began to replace their reliance in personal judgment with a trust in the impartial authority of numbers [12].

Enter Darwin

Darwinian thought was a key example of the challenge of scientific materialism in the nineteenth century. If humans were a part of nature, then they were subject to natural law. The notion of continuous variation was central to the new evolutionary thought. Coupled with an emerging notion of personhood as a relatively stable, skin-bound entity standing apart from professional function and social worth, Darwin’s ideas paved the way for measurement-based psychology. Late in the nineteenth century, Darwin’s cousin **Francis Galton** articulated key ideas for modern psychometrics, particularly the focus on human variation. The distribution of many physical attributes (e.g., height) had already been shown by **Quetelet** to approximate a Gaussian curve (*see Catalogue of Probability Density Functions*). Galton suggested that many psychological characteristics would show similar distributional properties. As early as 1816, Bessel had described ‘personal equations’ of systematic individual differences in astronomical observations. In contrast, some of the early psychologists of the modern era chose to ignore these types of differences. For instance, Wundt focused on common or fundamental mechanisms by studying a small number of subjects in-depth. Galton shifted psychologists’ attention to how individuals differed and by how much [8, 14].

Mental Testing Pioneers

Galton’s work was motivated by his obsession with eugenics. Widespread interest in the riddles of **heredity** provided considerable impetus to the development of psychometric testing. If many psychological properties were at least partly innate and inherited, then, arguably, it was even more important and useful to measure them. Galton was especially interested in intellectual functioning. By the mid-1880s, he had developed a diverse range of what (today) seem like primitive measures: tests of physical strength and swiftness, visual acuity and memory of forms. Galton was interested in how these measures related to each other, whether scores taken at an early age might predict later scientific or professional eminence, and whether eminence passed from one generation to the next. These were questions of agreement that were never going to be perfect. Galton needed an index

to calibrate the probabilistic rather than the deterministic relationship between two variables. He used **scatterplots** and noticed how scores on one variable were useful for predicting the scores on another and developed a measure of the ‘correlation’ of two sets of scores. His colleague, the biometric statistician **Karl Pearson** formalized and extended this work. Using the terms ‘normal curve’ and ‘standard deviation’ from the mean, Pearson developed what would become the statistical building blocks for modern psychometrics (e.g., the product-moment correlation (*see* **Pearson Product Moment Correlation**), multiple correlation (*see* **Multiple Linear Regression**), biserial correlation (*see* **Point Biserial Correlation**) [8, 13].

By the turn of the twentieth century, James Cattell and a number of American psychologists had developed a more elaborate set of anthropometric measures, including tests of reaction time and sensory acuity. Cattell was reluctant to measure higher mental processes, arguing these were a result of more basic faculties that could be measured more precisely. However, Cattell’s tests did not show consistent relationships with outcomes they were expected to, like school grades and later professional achievements. Pearson’s colleague and rival **Charles Spearman** argued this may have been due to the inherent unreliability of the various measures Cattell and others used. Spearman reasoned that any test would inevitably contain measurement error, and any correlation with other equally error-prone tests would underestimate the true correlation. According to Spearman, one way of estimating the measurement error of a particular test was to correlate the results of successive administrations. Spearman provided a calculation that corrected for this ‘attenuation’ due to ‘accidental error,’ as did William Brown independently, and both gave proofs they attributed to **Yule**. Calibrating measurement error in this way proved foundational. Spearman’s expression of the correlation of two composite measures in terms of their variance and covariance later became known as the ‘index of reliability’ [9].

Practical Measures

The first mental testers lacked effective means for assessing the qualities they were interested in. In France in 1905, Binet introduced a scale that provided a different kind of measurement. Binet did not

attempt to characterize intellectual processes; instead he assumed that performance on a uniform set of tasks would constitute a basis for a meaningful ranking of school children’s ability. Binet thought it necessary to sample complex mental functions, since these most resembled the tasks faced at school and provided for a maximum spread of scores [15].

Binet did not interpret his scale as a measure of innate intelligence; he insisted it was only a screening device for children with special needs. However, Goddard and many other American psychologists thought Binet’s test reflected a general factor in intellectual functioning and also assumed this was largely hereditary. Terman revised the Binet test just prior to World War II, paying attention to relevant cultural content and documenting the score profiles of various American age groups of children. But Terman’s revision (called the *Stanford–Binet*) remained an age-referenced scale, with sets of problems or ‘items’ grouped according to age appropriate difficulty, yielding an intelligence quotient mental age/chronological age (IQ) score.

Widespread use of Binet-style tests in the US army during World War I helped streamline the testing process and standardize its procedures. It was the first large-scale deployment of group testing and multiple-choice response formats with standardized tests [6, 16].

Branching Out

In the 1920s, criticism of interpretation of the Army test data – that the average mental age of soldiers, a large sample of the US population, was ‘below average’ – drew attention to the problem of appropriate ‘normative’ samples that gave meaning to test scores. The innovations of the subsequent Wechsler intelligence scales – with test results compared to a representative sample of adult scores – could be seen as a response to the limitations of younger age-referenced Binet tests. The interwar period also saw the gradual emergence of the concept of ‘validity,’ that is, whether the test measured what it was supposed to. Proponents of Binet-style tests wriggled out of the validity question with a tautology: intelligence was what intelligence tests measured. However, this stance was developed more formally as operationism, a stopgap or creative solution (depending on your point of view) to the problem of quantitative ontology. In the mid-1930s, **S. S. Stevens** argued that

the theoretical meaning of a psychological concept could be defined by the operations used to measure it, which usually involved the systematic assignment of number to quality. For many psychologists, the operations necessary to transform a concept into something measurable were taken as *producing* the concept itself [11, 14, 18].

The practical success of intelligence scales allowed psychologists to extend operationism to various interest, attitude, and personality measures. While pencil-and-paper questionnaires dated back to at least Galton's time, the new branch of testing appearing after World War I took up the standardization and group comparison techniques of intelligence scales. Psychologists took to measuring what were assumed to be dispositional properties that differed from individual to individual not so much in quality but in amount. New tests of personal characteristics contained short question items sampling seemingly relevant content. Questions usually had fixed response formats, with response scores combined to form additive, linear scales. Scale totals were interpreted as a quantitative index of the concept being measured, calibrated through comparisons with the distribution of scores of normative groups. Unlike intelligence scales, responses to interest, attitude, or personality inventory items were not thought of as unambiguously right or wrong – although different response options usually reflected an underlying psychosocial ordering. Ambiguous item content and poor relationships with other measures saw the first generation of personality and interest tests replaced by instruments where definitions of what was to be measured were largely determined by reference to external criteria. For example, items on the Minnesota Multiphasic Personality Inventory were selected by contrasting the responses of normal and psychiatric subject groups [3, 4].

Grafting on Theoretical Respectability

In the post World War II era, psychologists subtly modified their operationist approach to measurement. Existing approaches were extended and given theoretical rationalizations. The factor analytic techniques (*see* **Factor Analysis: Exploratory**) that Spearman, Thurstone, and others had developed and refined became a mathematical means to derive

latent concepts (*see* **Latent Variable**) from more directly measured variables [1, 10]. They also played a role in guaranteeing both the validity and reliability of tests, especially in the construction phase. Items could be selected that apparently measured the same underlying variable. Several key personality and attitude scales, such as the **R.B. Cattell's** 16 PF and Eysenck's personality questionnaires, were developed primarily using factor analysis. **Thurstone** used factor analysis to question the unitary concept of intelligence. New forms of item analyses and scaling (e.g., indices of item difficulty, discrimination, and consistency) also served to guide the construction of reliable and valid tests.

In the mid-1950s, the American Psychological Association stepped in to upgrade all aspects of testing, spelling out the empirical requirements of a 'good' test, as well as extending publishing and distribution regulations. They also introduced the concept of 'construct validity,' the test's conceptual integrity borne out by its theoretically expected relationships with other measures. Stung by damaging social critiques of cultural or social bias in the 1960s, testers further revived the importance of theory to a historically pragmatic field. Representative content coverage, relevant, and appropriate predictive criteria, all became keystones for fair and valid tests [5, 14].

The implications of Spearman's foundational work were finally formalized by Gulliksen in 1950, who spelt out the assumptions the classical 'true score model' required. The true score model was given a probabilistic interpretation by Lord and Novick in 1968 [17]. More recently, psychometricians have extended item level analyses to formulate generalized response models. Proponents of item response theory claim it enables the estimation of latent aptitudes or attributes free from the constraints imposed by particular populations and item sets [2, 7].

History of Surveys of Sexual Behavior

My own belief is that there is hardly anyone whose sexual life, if it were broadcast, would not fill the world at large with surprise and horror.

Somerset Maugham

Survey research (*see* **Survey Questionnaire Design**) is largely a product of the twentieth century, although there are some notable exceptions. In the last decade of the nineteenth century, for example, Charles Booth, a successful businessman and dedicated conservative, sought accurate data on the poor of London after becoming disturbed by a socialist claim that a third of the people in the city were living in poverty. But it is only in the past 70 to 80 years that survey research has become firmly established, particularly as market research, opinion polling, and election research. Among the factors that brought surveys into favour was the change from speculation to empiricism in social psychology and sociology – the demand that ‘hunches’ must be backed by numerical evidence, that is data.

Sample surveys provide a flexible and powerful approach to gathering information, but careful consideration needs to be given to various aspects of the survey if the information collected is to be accurate, particularly when dealing with a sensitive topic such as sexual behavior. If such surveys *are* to be taken seriously as a source of believable material a number of issues must be addressed, including;

- Having a sample that is truly representative of the population of interest. Can the sample be regarded as providing the basis for inferences about the target population? A biased selection process may produce deceptive results.
- Having a large enough sample to produce reasonably precise estimates of the prevalence of possibly relatively rare behaviors,
- Minimizing nonresponse. Nonresponse can be a thorny problem for survey researchers. After carefully designing a study, deciding on an appropriate sampling scheme, and devising an acceptable questionnaire, researchers often quickly discover that human beings can be cranky creatures; many of the potential respondents will not be at home (even after making an appointment for a specified

time), or will not answer the telephone, or have moved away, or refuse to reply to mail shots, and so generally make the researcher’s life difficult. In many large-scale surveys, it may take considerable effort and resources to achieve a response rate even as high as 50%. And nonresponse often leads to biased estimates.

- The questions asked. Do the questions illicit accurate responses? Asking questions that appear judgmental can affect the way people answer. The wording of questions by the interviewer or on the questionnaire is critical. Everyday English, as used in colloquial speech, is often ambiguous. For surveys, definitions of terms need to be precise to measure phenomena accurately. At the same time, the terms should be easily understood – technical terms should be avoided. This is not always easy because there are few terms that are universally understood. This is particularly true in surveys of sexual behavior. The meaning of terms such as ‘vaginal sex’, ‘oral sex’, ‘penetrative sex’ and ‘heterosexual’, for example, is taken for granted in much health education literature, but there is evidence that much misunderstanding of such terms exists in the general public.
- Are people likely to be truthful in their answers? Systematic distortion of the respondent’s true status clearly jeopardizes the validity of survey measurements. This problem has been shown even in surveys of relatively innocuous subject matter, owing in part to a respondent’s perceptions and needs that emerge during the data collection process. Consequently the potential for distortion to cause problems in surveys of sensitive information is likely to be considerable due to heightened respondent concern over anonymity. Of course, a person’s sex life is very likely to be a particularly sensitive issue. The respondents need to be assured about confidentiality and in face-to-face interviews the behavior of the interviewer might be critical.

In the end the varying tendencies among respondents to cooperate in surveys (particularly sex surveys), or to under-report/overreport if they respond, can easily lead to wildly inaccurate estimates of the extent of sensitive phenomena. There *are* techniques to collect sensitive information that largely remove the problem of under or over reporting by introducing an element of chance into the responses. These

2 History of Surveys of Sexual Behavior

techniques disguise the true response yet allow the researcher sufficient data for analysis. The most common of these techniques is the **randomized response** approach but there is little evidence of its use in the vast majority of investigations into human sexual behavior.

Surveys of Sexual Behavior

The possibility that women might enjoy sex was not considered by the majority of our Victorian ancestors. The general Victorian view was that women should show no interest in sex and preferably be ignorant of its existence unless married; then they must submit to their husbands without giving any sign of pleasure. A lady was not even supposed to be interested in sex, much less have a sexual response. (A Victorian physician, Dr. Acton, even went as far as to claim ‘It is a vile aspersion to say that women were ever capable of sexual feelings’.) Women were urged to be shy, blushing, and genteel. As Mary Shelley wrote in the early 1800s, ‘Coarseness is completely out of fashion.’ (Such attitudes might, partially at least, help explain both the increased interest in pornography amongst Victorian men and the parallel growth in the scale of prostitution.)

But in a remarkable document written in the 1890s by Clelia Mosher, such generalizations about the attitudes of Victorian women to matters sexual are thrown into some doubt, at least for a minority of women. The document, *Study of the Physiology and Hygiene of Marriage*, opens with the following introduction;

In 1892, while a student in biology at the University of Wisconsin, I was asked to discuss the marital relation in a Mother’s Club composed largely of college women. The discussion was based on replies given by members to a questionnaire.

Mosher probed the sex lives of 45 Victorian women by asking them whether they liked intercourse, how often they had intercourse, and how often they wanted to have intercourse. She compiled approximately 650 pages of spidery handwritten questionnaires but did not have the courage to publish, instead depositing the material in Stanford University Archives. Publication had to await the heroic efforts of James MaHood and his colleagues who collated and edited the questionnaires, leading in 1980 to their book, *The Mosher Survey* [9].

Clelia Mosher’s study, whilst not satisfactory from a sampling point-of-view because the results can in no way be generalized (the 45 women interviewed were, after all, mature, married, experienced, largely college-educated American women) remains a primary historical document of premodern sex and marriage in America. The reasons are clearly identified in [9];

... it contains statements of great rarity directly from Victorian women, whose lips previously had been sealed on the intimate questions of their private lives and cravings. Although one day it may come to light, we know of no other sex survey of Victorian women, in fact no earlier American sex survey of any kind, and certainly no earlier survey conducted by a woman sex researcher.

Two of the most dramatic findings of the Mosher survey are

- The Victorian women interviewed by Mosher appeared to relish sex, and claimed higher rates of orgasm than those reported in far more recent surveys.
- They practised effective birth-control techniques beyond merely abstinence or withdrawal.

For these experienced, college-educated women at least, the material collected by Mosher produced little evidence of Victorian prudery.

Nearly 40 years on from Mosher’s survey, Katharine Davis studied the sex lives of 2200 upper-middle class married and single women. The results of Davis’s survey are described in her book, *Factors in The Sex Life of Twenty Two Hundred Women*, published in 1929 [2]. Her stated aim was to gather data as to ‘normal experiences of sex on which to base educational programs’. Davis considered such normal sexual experiences to be, to a great extent, scientifically unexplored country. Unfortunately, the manner in which the eponymous women were selected for her study probably meant that these experiences were to remain so for some time to come.

Initially a letter asking for cooperation was sent to 10000 married women in all parts of the United States. Half of the addresses were furnished by a ‘large national organization’ (not identified by Davis). Recipients were asked to submit names of normal married women – ‘that is, women of good standing in the community, with no known physical, mental, or moral handicap, of sufficient

intelligence and education to understand and answer in writing a rather exhaustive set of questions as to sex experience'. (The questionnaire was eight pages long.)

Another 5000 names were selected from published membership lists of clubs belonging to the *General Federation of Women's Clubs*, or from the alumnae registers of women's colleges and coeducational universities.

In each letter was a return card and envelope. The women were asked to indicate on the card whether they would cooperate by filling out the questionnaire, which was sent only to women requesting it. This led to returned questionnaires from 1000 married women.

The unmarried women in the study were those five years out of a college education; again 10000 such women were sent a letter asking whether or not they would be willing to fill out, in their case, a 12-page questionnaire. This resulted in the remaining 1200 women in the study.

Every aspect of the selection of the 2200 women in Dr Davis's study is open to statistical criticism. The respondents were an unrepresentative sample, of volunteers who were educationally far above average and only about 10% of those contacted ever returned a questionnaire. The results are certainly not generalizable to any recognisable population of more universal interest. But despite its flaws a number of the charts and tables in the report retain a degree of fascination. Part of the questionnaire, for example, dealt with the use of methods of contraception. At the time, contraceptive information was categorized as obscene literature under federal law. Despite this, 730 of the 1000 married women who filled out questionnaires had used some form of contraceptive measure. Where did they receive their advice about these measures? Davis's report gives the sources shown in Table 1.

Davis along with most organizers of sex surveys also compiled figures on frequency of sex; these are shown in Table 2.

Davis's rationale for compiling the figures in Table 2 was to investigate the frequency of intercourse as a possible factor in sterility and for this purpose she breaks down the results in a number of ways. She found no evidence to suggest a relationship between marked frequency of intercourse and sterility – indeed she suggests that her results indicate the reverse.

Table 1 Sources of information about contraceptive measures (from [2])

Physicians	370
Married women friends	174
Husband	139
Mother	42
Friend of husband	39
Books	33
Birth-control circulars	31
'Common knowledge'	27
Nurse	15
Medical studies	9
'Various'	8
'Drug-store man'	6
The Bible	2
A servant	1
A psychoanalyst	1

Table 2 Frequency of intercourse of married women (from [2])

Answer	Number	Percent
More than once a day	19	2.0
Once a day	71	7.6
Over twice, less than seven times a week	305	31.3
Once or twice a week	391	40.0
One to three times a month	125	12.8
'Often' or 'frequently'	22	2.4
'Seldom' or 'infrequently'	38	3.9
Total answers to frequency questions	971	100
None in early years	8	
Unanswered (No answer)	21	
Total group	1000	

From a methodological point-of-view, one of the most interesting aspects of the Davis report is her attempt to compare the answers of women who responded by both interview and questionnaire. Only a relatively small number of women (50) participated in this comparison but in general there was a considerably higher incidence of 'sex practices' reported on the questionnaire. Davis makes the following argument as to why she considers the questionnaire results to be more likely to be closer to the truth;

In the evolutionary process civilization, for its own protection, has had to build up certain restraints on sexual instincts which, for the most part, have been in sense of shame, especially for sex outside of the legal sanction of marriage. Since sex practices prior to marriage have not the general approval of society, and since the desire for social approval is one of the

4 History of Surveys of Sexual Behavior

fundamental motives in human behavior, admitting such a practice constitutes a detrimental confession on the part of the individual and is more likely to be true than a denial of it. In other words, the group admitting the larger number of sex practices is assumed to contain the greater number of honest replies [2].

The argument is not wholly convincing, and would certainly not be one that could be made about the respondents in contemporary surveys of sexual behavior.

Perhaps the most famous sex survey ever conducted was the one by Kinsey and his colleagues in the 1940s. Alfred Charles Kinsey was undoubtedly the most famous American student of human sexual behavior in the first half of the twentieth century. He was born in 1894 and had a strict Methodist upbringing. Originally a biologist who studied *Cynipidae* (gall wasps), Kinsey was a professor of zoology, who never thought to study human sexuality until 1938, when he was asked to teach the sexuality section of a course on marriage. In preparing his lectures, he discovered that there was almost no information on the subject. Initially, and without assistance, he gathered sex histories on weekend field trips to nearby cities. Gradually this work involved a number of research assistants and was supported by grants from Indiana University and the Rockefeller Foundation.

Until Kinsey's work (and despite the earlier investigations of people like Mosher and Davis) most of what was known about human sexual behavior was based on what biologists knew about animal sex, what anthropologists knew about sex among natives in Non-Western, nonindustrialized societies, or what Freud and others learnt about sexuality from emotionally disturbed patients. Kinsey and his colleagues were the first psychological researchers to interview volunteers in depth about their sexual behavior. The research was often hampered by political investigations and threats of legal action. But in spite of such harassment, the first Kinsey report, *Sexual Behavior in the Human Male*, appeared in 1948 [7], and the second, *Sexual Behavior in the Human Female*, in 1953 [8]. It is no exaggeration to say that both caused a sensation and had massive impact. *Sexual Behavior in the Human Male*, quickly became a bestseller, despite its apparent drawbacks of stacks of tables, graphs, bibliography, and a 'scholarly' text that it is

kind to label as merely monotonous. The report certainly does not make for lively reading. Nevertheless, six months after its publication it still held second place on the list of nonfiction bestsellers in the USA. The first report proved of interest not only to the general public, but to psychiatrists, clergymen, lawyers, anthropologists, and even home economists. Reaction to it ranged all the way from extremely favourable to extremely unfavourable – here are some examples of both:

- The Kinsey Report has done for sex what Columbus did for geography,
- ... a revolutionary scientific classic, ranking with such pioneer books as Darwin's *Origin of the Species*, Freud's and Copernicus' original works,
- ... it is an assault on the family as the basic unit of society, a negation of moral law, and a celebration of licentiousness,
- there should be a law against doing research dealing exclusively with sex.

What made the first Kinsey report the talk of every town in the USA lies largely in the following summary of its main findings:

Of American males,

- 86% have premarital intercourse by the age of 30,
- 37%, at some time in their lives, engaged in homosexual activity climaxed by orgasm,
- 70% have, at some time, intercourse with prostitutes,
- 97% engage in forms of sexual activity, at some time in their lives, that are punishable as crimes under the law,
- of American married males, 40% have been involved in extramarital relations,
- of American farm boys, 16% have sexual contacts with animals.

These figures shocked because they suggested that there was much more sex, and much more variety of sexual behavior amongst American men than was suspected.

But we need to take only a brief look at some of the details of Kinsey's study to see that the figures above and the many others given in the report hardly stand up to statistical scrutiny.

Although well aware of the scientific principles of sampling, Kinsey based all his tables, charts, and so on, on a total of 5300 interviews with volunteers. He knew that the ideal situation would have

been to select people at random, but he did not think it possible to coax a randomly selected group of American males to answer truthfully when asked deeply personal questions about their sex lives. Kinsey sought volunteers from a diversity of sources so that all types would be sampled. The work was, for example, carried on in every state of the Union, and individuals from various educational groups were interviewed. But the 'diversification' was rather haphazard and the proportion of respondents in each cell did not reflect the United States population data. So the study begins with the disadvantage of volunteers and without a representative sample in any sense. The potential for introducing bias seems to loom large since, for example, those who volunteer to take part in a sex survey might very well have different behavior, different experiences, and different attitudes towards sex than the general population. In fact, recent studies show that people who volunteer to take part in surveys about sexual behavior are likely to be more sexually experienced and also more interested in sexual variety than those who do not volunteer.

A number of procedures were used by Kinsey to obtain interviews and to reduce refusals. Contacts were made through organizations and institutions that in turn persuaded their members to volunteer. In addition, public appeals were made and often one respondent would recommend another. Occasionally, payments were given as incentives. The investigators attempted to get an unbiased selection by seeking all kinds of histories and by long attempts to persuade those who were initially hostile to come into the sample. In a two-hour interview, Kinsey's investigators covered from 300 to 500 items about the respondent's sexual history, but no sample questionnaire is provided in the published report. The definition of each item in the survey was standard, but the wording of the questions and the order in which they were given were varied for each respondent. In many instances leading questions were asked such as, '*When did you last . . .*' or '*When was the first time you . . .*', thereby placing the onus of denial on the respondent. The use of leading questions is generally thought to lead to the overreporting of an activity. Kinsey's aim was to provide the ideal setting for each individual interview whilst retaining an equivalence in the interviews administered to all respondents. So the objective conditions of the interview were not uniform and variation in sexual behavior between

individuals might be confounded with differences in question wording and order.

The interview data in the Kinsey survey were recorded in the respondent's presence by a system of coding that was consigned to memory by all six interviewers during the year-long training that preceded data collection. Coding in the field has several advantages such as speed and the possibility of clarifying ambiguous answers; memory was used in preference to a written version of the code to preserve the confidence of the interviewee. But the usual code ranged from six to twenty categories for each of the maximum of 521 items that could be covered in the interview, so prodigious feats of memory were called for. One can only marvel at the feat. Unfortunately, although field coding was continually checked, no specific data on the reliability of coding are presented and there has to be some suspicion that occasionally, at least, the interviewer made coding mistakes.

Memory certainly also played a role in the accuracy of respondent's answers to questions about events which might have happened long ago. It's difficult to believe, for example, that many people can remember details of frequency of orgasm per week, per five-year period, but this is how these frequencies are presented. Many of the interviews in the first Kinsey report were obtained through the cooperation of key individuals in a community who recommended friends and acquaintances, and through the process of developing a real friendship with the prospective respondent before starting the interview as the following quotation from the report indicates:

We go with them to dinner, to concerts, to nightclubs, to the theatre, we become acquainted with them at community dances and in poolrooms and taverns, and in other places which they frequent. They in turn invite us to meet friends in their homes, at teas, at dinners, at other social events [7, p. 40].

This all sounds very pleasant both for the respondents and the interviewers but is it good survey research practice? Probably not, since experience suggests that the 'sociological stranger' gets the more accurate information in a sensitive survey, because the respondent is wary about revealing his most private behavior to a friend or acquaintance. And assuming that all the interviewers were white males the question arises as to how this affected interviews with say, African-American respondents (and in the second report, with women)?

Finally there are some more direct statistical criticisms that can be levelled at the first Kinsey report. There is, for example, often a peculiar variation in the number of cases in a given cell, from table to table. A particular group will be reported on one type of sexual behavior, and this same group may be of slightly different size in another table. The most likely explanation is that the differences are due to loss of information through 'Don't know' responses or omissions of various items, but the discrepancies are left unexplained in the report. And Kinsey seems shaky on the definition of terms such as median although this statistic is often used to summarize findings. Likewise he uses the sample **range** as a measure of how much particular measurements varied amongst his respondents rather than the preferable standard deviation statistic.

Kinsey addressed the possibility of bias in his study of male sexual behavior and somewhat surprisingly suggested that any lack of validity in the reports he obtained would be in the direction of concealment or understatement. Kinsey gives little credence to the possibility of overstatement:

Cover-up is more easily accomplished than exaggeration in giving a history [7, p. 54].

Kinsey thought that the interview approach provided considerable protection against exaggeration but not so much against understatement. But given all the points made earlier this claim is not convincing, and it is not borne out by later, better-designed studies, which generally report lower levels of sexual activity than Kinsey. For example, the 'Sex in America' survey [10] was based on a representative sample of Americans and it showed that individuals were more monogamous and more sexually conservative than had been reported previously.

Kinsey concludes his first report with the following.

We have performed our function when we have published the record of what we have found the human male doing sexually, as far as we have been able to ascertain the facts.

Unfortunately, the 'facts' arrived at by Kinsey and his colleagues may have been distorted in a variety of ways because of the many flaws in the study. But despite the many methodological errors, Kinsey's studies remain gallant attempts to survey the approximate range and norms of sexual behavior.

The Kinsey report did have the very positive effect of encouraging others to take up the challenge of investigating human sexual behavior in a scientific and objective manner. In the United Kingdom, for example, an organization known as *Mass-Observation* carried out a sex survey in 1949 that was directly inspired by Kinsey's first study. In fact it became generally known as 'Little Kinsey' [3]. Composed of three related surveys, 'Little Kinsey' was actually very different methodologically from its American predecessor. The three components of the study were as follows:

1. A 'street sample' survey of over 2000 people selected by random sampling methods carried out in a wide cross section of cities, towns and villages in Britain.
2. A postal survey of about 1000 each of three groups of 'opinion leaders': clergymen, teachers, and doctors.
3. A set of interrelated questions sent to members of Mass-Observation's National Panel, which produced responses from around 450 members.

The report's author, Tom Harrison, was eager to get to the human content lying behind the line-up of percentages and numbers central to the Kinsey report proper, and he suggested that the Mass-Observation study was both 'something less and something more than Kinsey'. It tapped into 'more of the actuality, the real life, the personal stuff of the problem'. He tried to achieve these aims by including in each chapter some very basic tables of responses, along with large numbers of comments from respondents to particular questions. Unfortunately this idiosyncratic approach meant that the study largely failed to have any lasting impact, although later authors, for example, Liz Stanley in *Sex Surveyed 1949-1994* [11], claim it was of pioneering importance and was remarkable for pinpointing areas of behavioral and attitudinal change. It does appear to be one of the earliest surveys of sex that used random sampling. Here are some of the figures and comments from Chapter 7 of the report, *Sex Outside Marriage*.

The percentages who disapproved of extramarital relations were

- 24% on the National Panel,
- 63% of the street sample,
- 65% of doctors,
- 75% of teachers,

- 90% of clergymen.

Amongst the street sample the following percentages were given for those opposed to extramarital relations:

- 73% of all weekly churchgoers,
- 54% of all non-churchgoers,
- 64% of people leaving school up to and including 15 years,
- 50% of all leaving school after 16,
- 68% of all living in rural areas,
- 50% of all Londoners,
- 67% of all women,
- 57% of all men,
- 64% of all married people over 30,
- 48% of all single people over 30.

The Kinsey report, 'Little Kinsey2', and the surveys of Clelia Mosher and Katherine Davis, represent, despite their flaws, genuine attempts at taking an objective, scientific approach to information about sexual behavior. But sex, being such a fascinating topic also attracts the more sensational commercial 'pseudosurveys' like those regularly conducted amongst the readership of magazines such as *Playboy* and *Cosmopolitan*. Here the questions asked are generally a distinctly 'racier' variety than in more serious surveys. Here is just one example:

- When making love, which of the following do you like? (check all that apply)
 1. Have your man undress you
 2. Pinch, bite, slap him
 3. Be pinched, bitten, slapped
 4. Have someone beat you
 5. Pretend to fight physically with the man or try to get away.

The aims of these surveys are to show that the readership of the magazine enjoys sexually exciting lives, to celebrate their reader's 'sexual liberation' and to make the rest of us green eyed with envy (or red faced with shame). The results are generally presented in the form of tabloid type headlines, for example;

French have more sex than Englishmen.

Such surveys are, essentially, simply sources of fun, fantasy, and profit and can, of course, be easily dismissed from serious consideration because of their obvious biases, clear lack of objectivity, poor sampling methods and shoddy questionnaire design.

Unfortunately, there have been several surveys of sexual behavior that demand to be taken seriously, but to which the same criticisms can be applied, and where, in addition, attempts to interpret the findings of the survey may have been colored by the likely *a priori* prejudices of the survey's instigator. One such example is the basis of that 1976 bestseller, *The Hite Report on Female Sexuality* [6].

Shire Hite is a member of the *National Organization of Women* and an active feminist. When she undertook her study in the 1970s, the aim of which she stated as 'to define or discover the physical nature of [women's] sexuality', she clearly had a feminist political axe to grind. — 'Most sex surveys have been done by men' she said and nobody had asked women the right questions. She wanted 'women to be experts and to say what female sexuality was about'. However, Dr Hite often appeared to have a strong prior inkling of what her respondents would tell her and such clear expectations of results are a matter of concern. First, we consider the methodology underlying the Hite report.

Hite sent questionnaires to 'consciousness-raising', abortion rights, and other women's groups and also advertised for respondents in newspapers and magazines, including *Ms.*, *Mademoiselle* and *Brides*. Of the 100 000 questionnaires distributed, Hite received somewhat more than 3000 responses, a response rate, she claimed, that was standard for surveys of this type. However, most serious survey researchers would regard 3% as very low. So the survey begins with an extremely biased sample and a very low response rate.

A further problem was that the questionnaire used in the study was hard to complete. Each question contained multiple subquestions, never a good idea in any survey. In addition, the survey began with numerous questions about orgasm rather than with more innocuous questions. Many questions called for 'essay-like' responses and others asked for seemingly impossible details from past events. Here are some examples:

- Do you have orgasms? If not, what do you think would contribute to your having them?
- Do you always have orgasms during the following (please indicate whether always, usually, sometimes, rarely, or never):
 1. Masturbation,
 2. Intercourse (vaginal penetration),

3. Manual clitoral stimulation by partner,
 4. Oral stimulation by a partner,
 5. Intercourse plus manual clitoral stimulation,
 6. Never have orgasms.
- Also indicate above how many orgasms you usually have during each activity, and how long you usually take.
 - Please give a graphic description of how your body could best be stimulated to orgasm.

Hite's questionnaire began with items about orgasm and much of her book dwells on her interpretation of the results from these items. She concludes that women can reach orgasm easily through masturbation but far less easily, if at all, through intercourse with their male partners. Indeed, one of her main messages is that intercourse is less satisfying to women than masturbation. She goes on to blame what she sees as the sorry state of female sexual pleasure in patriarchal societies, such as the United States, that glorify intercourse. Critics pointed out that there may be something in all of this, but that Hite was being less than honest to suppose that her views were an inescapable conclusion from the results of her survey. As the historian Linda Gordon pointed out [5], the Hite report was orientated towards young, attractive, autonomous career women, who were focused on pleasure and unencumbered by children. These women could purchase vibrators, read the text, and undergo the self-improvement necessary for one-person sexual bliss.

The Hite report has severe methodological flaws and these are compounded by the suspicion that its writer is hardly objective about the issues under investigation. The numbers are neither likely to have accurately reflected the facts, nor to have been value-free.

(It is not, of course, feminist theory that is at fault in the Hite report, as the comprehensive study of sex survey research given in [4], demonstrates; these two authors combine feminist theory with a critical analysis of survey research to produce a well-balanced and informative account.)

If the Hite Report was largely a flash in the media pan (Sheer Hype perhaps?), the survey on sexual attitudes and lifestyles undertaken in the UK in the late 1980s and early 1990s by Kaye Wellings and her coworkers [12] acts as a model of excellence for survey research in such a sensitive area. The impetus for the survey was the emergence of the HIV pandemic, and the attendant effort to assess and

control its spread. The emergence in the 1980s of a lethal epidemic of sexually transmitted infection focused attention on the profound ignorance that still remained about many aspects of sexual behavior, despite Kinsey and others. The collaboration of epidemiologists, statisticians, and survey researchers produced a plan and a survey about sex in which all the many problems with such surveys identified earlier were largely overcome.

A feasibility study assessed the acceptability of the survey, the extent to which it would produce valid and reliable results, and the sample size needed to produce statistically acceptable accuracy in estimates of minority behavior. The results of the feasibility study guided the design of the final questionnaire that was used in obtaining results from a carefully selected random sample of individuals representative of the general population. Of the 20 000 planned interviews 18876 were completed. Nonresponse rates were generally low. The results provided by the survey give a convincing account of sexual lifestyle in Britain at the end of the twentieth century. For interest one of the tables from the survey is reproduced in Table 3. The impact of AIDS has also been responsible for an increasing number of surveys about sexual behavior in the developing world, particularly in parts of Africa. A comprehensive account of such surveys is given in [1].

Summary

Since 1892 when a biology student, Clelia Mosher, questioned 45 upper middle-class married Victorian women about their sex lives, survey researchers have asked thousands of people about their sexual behavior. According to Julia Ericksen [4] in *Kiss and Tell*, 'Sexual behavior is a volatile and sensitive topic, and surveys designed to reveal it have great power and great limits'. Their power has been to help change, radically change in particular aspects, attitudes about sex compared to 50 years ago. Their limits have often been their methodological flaws. And, of course, when it comes to finding out about their sexual behavior, people may not want to tell, and even if they agree to be interviewed they may not be entirely truthful. But despite these caveats the information from many of the surveys of human sexual behavior has probably helped remove the conspiracy of silence about sex that existed in society, which condemned

Table 3 Number and percent of respondents taking part in different sexual practices in the last year and ever, by social class (from [12])

	Vaginal intercourse			Oral sex

many men and women to a miserable and unfulfilling sex life. The results have challenged views of the past 100 years that sex was not central to a happy marriage and that sex, as a pleasure for its own sake, debased the marital relationship. Sex as pleasure is no longer regarded by most people as a danger likely to overwhelm the supposedly more spiritual bond between a man and a woman thought by some to be achieved when sex occurs solely for the purposes of reproduction. Overall the information about human sexual behavior gathered from sex surveys has helped to promote, all be it in a modest way, a healthier attitude toward sexual matters and perhaps a more enjoyable sex life for many people.

Hodges–Lehman Estimator

The Hodges–Lehmann one-sample estimator provides a valuable alternative to the sample mean or median as an estimator of the location of the center of a distribution. While the median is to be preferred to the mean with nonsymmetric populations, it requires far more observations than the mean to obtain the same level of precision. The median’s **asymptotic relative efficiency** with respect to the mean for data from a normal population is only 0.64. By contrast, while the Hodges–Lehmann estimator offers the same advantages as the median, its asymptotic relative efficiency with respect to the mean is 0.96 for similar data [2].

The one-sample estimator, based on a random sample of n observations, is linked with the **Wilcoxon signed-rank test** [1] and is defined as the median of the set of $[n(n+1)/2]$ **Walsh averages**. Each Walsh average is the arithmetic average of a pair of observations, including observations paired with themselves.

The sample (2, 5, 7, 11), for example, gives rise to the 10 Walsh averages tabled below (Table 1).

The median of the set of Walsh averages is the one-sample Hodges–Lehmann estimator. For our example, with ten Walsh averages, the median estimate is the average of the fifth and sixth smallest Walsh averages, $(6 + 6.5)/2 = 6.25$.

The Hodges–Lehmann two-sample estimator provides an alternative to the difference in sample means when estimating a shift in location between two population distributions. The location shift model associated with the Wilcoxon Mann-Whitney test postulates that, while the two distributions are alike in shape and variability, the Y distribution is shifted upward or downward by an amount Δ relative to the X distribution [1]. The model is usually stated in terms of the relation between the cumulative probabilities for the two distributions: $Prob[Y \leq z] = Prob[X \leq (z - \Delta)]$, for all values of z . Positive values of Δ are associated with larger values in the Y than in the X distribution.

Let $(x_1, x_2, \dots, x_n)$ and $(y_1, y_2, \dots, y_m)$ be independent random samples from the X and Y distributions, respectively. The Hodges–Lehmann estimate of Δ is the median of the $(n \times m)$ pairwise differences, $(y_j - x_k)$, $j = 1, \dots, m$, $k = 1, \dots, n$.

For the two samples $x = (2, 5, 7, 11)$ and $y = (3, 4, 8, 20)$, the relevant pairwise differences are displayed in the table below (Table 2).

The median of the 16 pairwise differences is the average of the eighth and ninth smallest differences. As both of these differences are 1, the Hodges–Lehmann estimate is 1.0. The difference-in-means estimate of Δ , by comparison, is $(35/4) - (25/4) = 2.5$. The latter estimator is much more sensitive to outliers.

The author gratefully acknowledges the assistance of Phillip Good in the preparation of this article.

Table 1 Computation of one-sample Walsh averages

	2	5	7	11
2	$(2 + 2)/2 = 2$	$(2 + 5)/2 = 3.5$	$(2 + 7)/2 = 4.5$	$(2 + 11)/2 = 6.5$
5		$(5 + 5)/2 = 5$	$(5 + 7)/2 = 6$	$(5 + 11)/2 = 8$
7			$(7 + 7)/2 = 7$	$(7 + 11)/2 = 9$
11				$(11 + 11)/2 = 11$

Table 2 Computations of two-sample Walsh averages

$x \setminus y$	3	4	8	20
2	$(3 - 2) = 1$	$(4 - 2) = 2$	$(8 - 2) = 6$	$(20 - 2) = 18$
5	$(3 - 5) = -2$	$(4 - 5) = -1$	$(8 - 5) = 3$	$(20 - 5) = 15$
7	$(3 - 7) = -4$	$(4 - 7) = -3$	$(8 - 7) = 1$	$(20 - 7) = 13$
11	$(3 - 11) = -8$	$(4 - 11) = -7$	$(8 - 11) = -3$	$(20 - 11) = 9$

Horseshoe Pattern

Horseshoe Effect

All forms of **multidimensional scaling** have as their aim the low-dimensional representation of a set of proximity data (*see Proximity Measures*). A classic example is the recreation of a map from a matrix of say intercity road distances in a country. Often, such a map can be successfully recreated if only the ranking of the distances is given (*see [2]*). With such data, the underlying structure is essentially two-dimensional, and so can be represented with little distortion in a two-dimensional scaling solution. But when the observed data have a one-dimensional structure, for example, in a chronological study, representing the observed proximities in a two-dimensional scaling solution often gives rise to what is commonly referred to as the *horseshoe effect*. This effect appears to have been first identified in [2] and can be illustrated by the following example:

Consider 51 objects, $O_1, O_2, \dots, O_{51}$ assumed to be arranged along a straight line with the j th object being located at the point with coordinate j . Define the similarity, s_{ij} , between object i and object j , as, follows:

$$s_{ij} = \begin{cases} 9 & \text{if } i = j, \\ 8 & \text{if } 1 \leq |i - j| \leq 3, \\ 7 & \text{if } 4 \leq |i - j| \leq 6, \\ \vdots & \\ 1 & \text{if } 22 \leq |i - j| \leq 24 \\ 0 & \text{if } |i - j| \geq 25 \end{cases} \quad (1)$$

Next, convert these similarities into dissimilarities, δ_{ij} , using $\delta_{ij} = (s_{ii} + s_{jj} - 2s_{ij})^{1/2}$ and then apply *classical multidimensional scaling* (*see Multidimensional Scaling*) to the resulting dissimilarity matrix. The two-dimensional solution is shown in Figure 1. The original order has been reconstructed very well, but the plot shows the characteristic horseshoe shape,

Figure 1 An example of the horseshoe effect

which is a consequence of the ‘blurring’ of the large distances and is characteristic of such situations.

Further discussion of the horseshoe effect is given in [3] and some examples of its appearance in practice are described in [1].

Hotelling, Howard

Born: September 29, 1895, Minnesota, USA.

Died: December 26, 1973, North Carolina, USA.

Although Howard Hotelling was born in Fulda, Minnesota in 1895, he spent most of his childhood and young adulthood in Seattle, Washington. He attended the University of Washington, graduating in 1919 with a bachelor's degree in journalism. As an undergraduate student, Hotelling worked for several local newspapers. While still an undergraduate, he took a mathematics class taught by Eric Temple Bell. Bell recognized Hotelling's unusual analytic capabilities and encouraged him to do graduate work in mathematics. Hotelling earned a master's degree in mathematics from the University of Washington in 1921 and a Ph.D. in mathematics from Princeton University in 1924. In 1925, he published an article, 'Three-dimensional Manifolds of States of Motion', based on his dissertation in the *Transactions of the American Mathematical Society* [1].

From 1925 to 1931, Hotelling taught probability and statistics at Stanford University. During these years, Hotelling applied newly developed statistical techniques to areas as diverse as journalism, political science, and economics. His interests in statistics led him in 1929 to study with **R. A. Fisher** at the Rothamsted Experimental Station, an agricultural research institute in Hertfordshire, UK.

In 1931, Hotelling went to Columbia University as a professor of economics, where he stayed until 1946. During the 15 years Hotelling was at Columbia, the statistical research group he founded lent statistical assistance to the United States' military efforts in WWII. This statistical research group, which counted Abraham Wald among its many prominent members, introduced and developed sequential analysis. Sequential analysis proved to be so useful to the US military that the technique itself was considered to be classified information until the end of WWII.

In 1946, Hotelling moved from Columbia University to the University of North Carolina at Chapel Hill, where he founded a department of statistics. Hotelling remained at the University of North Carolina for the remainder of his professional life. He received a number of honors, including an honorary LL.D. from the University of Chicago, and

an honorary D.Sc. from the University of Rochester. He was an honorary fellow of the Royal Statistical Society and a distinguished fellow of the American Economic Association. He was president of the Econometric Society from 1936 to 1937 and of the Institute of Mathematical Statistics in 1941. The National Academy of Sciences elected him as a member in 1972. In May of 1972, he experienced a severe stroke; his death following in December of 1973.

Hotelling's greatest contributions to statistics were in the general areas of econometrics and multivariate analysis. In econometrics, Hotelling's 1929 paper on the stability of competition introduced the idea of spatial competition, known as 'Hotelling's model', when there are only two sellers competing in a market [2]. The solution to this problem was an early statement of the **game theory** concept of the 'Subgame-perfect equilibrium', although Hotelling did not refer to it as such. Hotelling introduced the calculus of *variations* to economics in 1931 as a method of analyzing resource exhaustion [4]. Although Hicks and Allen are generally credited in 1934 with explaining the downward slope of demand curves, Hotelling, in fact, also in that year, had independently derived an identical solution. (The paper describing his solution did not, however, appear until 1935, [7]). In 1938, Hotelling introduced the concept of 'marginal cost pricing' equilibrium: Economic efficiency is achieved if every good is produced and priced at marginal cost. At the same time, he introduced the 'two-part' tariff as a solution to situations of natural monopoly [9].

Hotelling's contributions to multivariate analysis were many, among the more important of which was his multivariate generalization of Student's t Test in 1931 [5] – now known as Hotelling's T^2 . Hotelling also proposed the methods of **principal component analysis** [6] and **canonical correlations** [8]. His paper (cowritten by Working) on the interpretation of trends contains the first example of a confidence region, as well as multiple comparisons [11]. His contributions (with Richards) to the theory of rank statistics (*see Rank Based Inference*) were also highly influential [10]. This work grew out of his interest in specifying the precise conditions for the consistency and asymptotic normality of **maximum likelihood estimates** [3]. Hotelling was always clear that he was a statistician first, econometrician second.

Hull, Clark L

Born: May 24, 1884, in New York State.

Died: May 10, 1952, in Connecticut.

Clark L. Hull embraced behaviorism from the start of his academic career in psychology: his Ph.D. in 1918, for example, offered a behavioral recasting of concept acquisition as a *quantitative* form of learning, in contrast to the heavy emphasis on introspection and philosophy, which characterized contemporary work on thinking and reasoning. He also took up classical conditioning after the American publication of Pavlov's *Conditioned Reflexes* in 1927, followed by Thorndike's law of effect, thus melding reinforcement to associationism as the basis of all learning. But his most important contribution to psychology was to pioneer mathematical models of learning. It is, of course, the case that there had been some attempts to formally model behavior before Hull (see Miller [3], for an elementary and now classic introduction to the field), but his was the most ambitious attempt prior to the advent of today's more sophisticated forms of mathematical psychology.

His early days had been very difficult, not only because of the poverty of his parents and the hard work involved in helping them run their farm but also because he had suffered a debilitating bout of typhoid fever in 1905, having just graduated from Alma College with the aim of eventually becoming a mining engineer. Even worse was the attack of poliomyelitis at the age of 24, which left him with a paralyzed leg and a lifelong fear both of illness and that he might not live long enough to accomplish his goals. Clearly, a career in mining was now out of question, so Hull opted for a degree in psychology at the University of Michigan, graduating after two years study with an A.B. and a Teachers diploma. After a year teaching at a Normal School in Kentucky, which had been set up to educate teachers, Hull was finally accepted for graduate work at the University of Wisconsin under Joseph Jastrow. An M.A. was quickly obtained in 1915, followed by a Ph.D. in 1918, the latter appearing as a monograph in 1920. Hull's career was now, after many setbacks, on an upward trajectory: he became a full professor at Wisconsin in 1925, for instance, and had published his first book (on aptitude measurement) in 1928.

More important, however, was his move to Yale's Institute of Psychology in 1929 as an expert on test theory, although he had quickly abandoned this research area in favor of learning and conditioning, although not without some internal bickering. The effective incorporation of the Institute of Psychology into the much larger and more generously funded Institute of Human Relations at Yale, together with a more sympathetic head of the Institute, meant that Hull could now indulge in his lifelong passion. This resulted in a flow of experimental and theoretical papers in the 1930s, which pushed the study of learning to new heights of sophistication, with Hull and his occasional rival Edward C. Tolman being increasingly cited as the only game in town.

What Hull did was essentially to model the so-called learning curve, that is, the growth in learning or extinction over trials. The models used to capture such curves were almost exclusively exponential in form, although Hull was not averse to employing more than one exponential function to model a particular data set. Underlying the models was an elaborate internal mechanism designed to reflect the effects of such factors as reinforcement, stimulus and response generalization, excitation and inhibition (of the Pavlovian variety), and behavioral fluctuation or oscillation (to use his term) on learning. This turned into a considerable program of research that was supported by a large number of graduate students and Institute staff, and was organized on an almost industrial or military scale. Hull was also happy to use data produced by other laboratories provided that the quality of their work satisfied Hull's own exacting standards. He also ransacked the journals for good quality data. Consequently, his *magnum opus* of 1943, *The Principles of Behavior* [1], mixed mathematics and data not just from the Yale laboratory but from an international collection of research sources. This book had followed a much more indigestible monograph on modeling rote learning that had appeared in mimeograph form in 1940 and in which the full rigor of fitting exponential functions to learning was laid out for the first time.

The two books also revealed the weaknesses in Hull's approach in that the fitting process did not use contemporary statistical methods like **least squares**, and the models themselves were historically somewhat antiquated. Thus, Hull fitted the data by eye and by reiterated fitting alone, after having selected the exponential function on highly informal grounds.

The structure of the models was also essentially deterministic in that the only random variable was error, that is, behavioral oscillation, which was added to the fixed effects of reinforcement, stimulus generalization, and so on, in order to account for the results.

The last years of Hull's life were dogged by increasing ill health, and he was only able to publish the updated and expanded version of the *Principles, A Behavior System* [2], in 1962, the year of his death. Hull fought against considerable personal and bureaucratic odds to demonstrate that learning, the most self-consciously *scientific* area of all experimental psychology, could be moved that much closer to

respectability through the application of mathematics to data.

Identification

A prerequisite for the estimation of the parameters of any model is to establish whether the parameters of the model are *identified*. Identification refers to whether the parameters of the model can be uniquely determined from the data. If the parameters of the model are not identified, estimation of the parameters is not possible. Although the problem of identification is present in almost all parametric statistical models, the role of identification is perhaps clearest in the context of covariance structure models. Here, we will define the problem of identification from the **covariance structure modeling** perspective. Later, we will introduce the problem of identification from the simultaneous equation modeling perspective when considering some simple rules for establishing identification. As simultaneous equation modeling can be seen as a special case of covariance structure modeling, this discussion is quite general.

Definition of Identification

We begin with a definition of *identification* from the perspective of covariance structure modeling. The advantage of this perspective is that covariance structure modeling includes, as a special case, the simple linear regression model, and, therefore, we can understand the role of identification even in this simple case. First, arrange the unknown parameters of the model in the vector Ω . Consider next a population covariance matrix Σ whose elements are population variances and covariances (*see Correlation and Covariance Matrices*). It is assumed that a substantive model can be specified to explain the variances and covariances contained in Σ . Such a substantive model can be as simple as a two-variable linear regression model or as complicated as a simultaneous equation model. We know that the variances and covariances contained in Σ can be estimated by their sample counterparts in the sample covariance matrix S using straightforward formulae for the calculation of sample variances and covariances. Thus, the parameters in Σ are identified.

Having established that the elements in Σ are identified from their sample counterparts, what we need to establish in order to permit estimation of the model parameters is whether the model parameters

are identified. By definition, we say that the elements in Ω are *identified* if they can be expressed uniquely in terms of the elements of the covariance matrix Σ . If all elements in Ω are identified, we say that the model is identified.

Some Common Identification Rules

Let us now consider the identification of the parameters of a general simultaneous equation model that can be written as

$$y = By + \Gamma x + \zeta, \quad (1)$$

where y is a vector endogenous variable that the model is specified to explain, x is a vector exogenous variable that is purported to explain y but whose behavior is not explained, ζ is a vector of disturbance terms, and B and Γ are coefficient matrices. Note that when $B = 0$, we have the **multivariate multiple regression** model

$$y = \Gamma x + \zeta. \quad (2)$$

When the vector of endogenous variables contains only one column (i.e., only one explanatory variable is considered), then we have the case of simple linear regression.

To begin, we note that there exists an initial set of restrictions that must be imposed even for simple regression models. The first restriction, referred to as *normalization*, requires that we set the diagonal elements of B to zero, such that an endogenous variable cannot have a direct effect on itself.

The second requirement concerns the vector of disturbance terms ζ . Note that the disturbances for each equation are unobserved, and, hence, have no inherent metric. The most common way to set the metric of ζ , and the one used in simple regression modeling, is to fix the coefficient relating the endogenous variables to the disturbance terms to 1.0. An inspection of (2) reveals that ζ is actually being multiplied by the scaling factor 1.0. Thus, the disturbance terms are in the same scale as their relevant endogenous variables.

With the normalization rule in place and the metric of ζ fixed, we can now discuss some common rules for the identification of simultaneous equation model parameters. Recall again that we wish to know whether the variances and covariances of the

2 Identification

exogenous variables (contained in Φ), the variances and covariances of the disturbance terms (contained in Ψ), and the regression coefficients (contained in B and Γ) can be solved in terms of the variances and covariances contained in Σ .

Two classical approaches to identification can be distinguished in terms of whether identification is evaluated on the model as a whole, or whether identification is evaluated on each equation comprising the system of simultaneous equations. The former approach is generally associated with social science applications of simultaneous equation modeling, while the latter approach appears to be favored in the econometrics field applied mainly to simultaneous (i.e., nonrecursive) models. Nevertheless, they both provide a consistent picture of identification in that if any equation is not identified, the model as a whole is not identified.

The first, and perhaps simplest, method for ascertaining the identification of the model parameters is referred to as the *counting rule*. Let $s = p + q$ be the total number of endogenous and exogenous variables, respectively. Then the number of nonredundant elements in Σ is equal to $1/2 s(s + 1)$. Let t be the total number of parameters in the model that are to be estimated (i.e., the free parameters). Then, the counting rule states that a necessary condition for identification is that $t \leq 1/2 s(s + 1)$. If the equality holds, then we say that the model may be *just identified*. If t is strictly less than $1/2 s(s + 1)$, then we say that the model may be *overidentified*. If t is greater than $1/2 s(s + 1)$, then the model may be *not identified*.

Clearly, the advantage to the counting rule is its simplicity. However, the counting rule is a necessary but not sufficient rule. We can, however, provide rules for identification that are sufficient, but that pertain only to recursive models, or special cases of recursive models. Specifically, a sufficient condition for identification is that B is triangular and that Ψ is a diagonal matrix. However, this is the same as saying that recursive models are identified. Indeed, this is the case, and [1] refers to this rule as the *recursive rule* of identification. In combination with the counting rule above, recursive models can be either just identified or overidentified.

A special case of the recursive rule concerns the situation where $B = 0$ and Ψ again a diagonal matrix. Under this condition, the model in (1) reduces to the model in (2). Here too, we can utilize the

counting rule to show that regression models are also just identified.

Note that recursive models place restrictions on the form of B and Ψ and that the identification conditions stated above are directly related to these types of restrictions. Nonrecursive models, however, do not restrict B and Ψ in the same way. Thus, we need to consider identification rules that are relevant to nonrecursive models.

As noted above, the approach to identification arising out of econometrics (see [2]), considers one equation at a time. The concern is whether a true simultaneous equation can be distinguished from a false one formed by a linear combination of the other equations in the model (see [3]). In complex systems of equations, trying to determine linear combinations of equations is a tedious process. One approach would be to evaluate the rank of a given matrix, because if a given matrix is not of full rank, then it means that there exist columns (or rows) that are linear combinations of each other. This leads to developing a *rank condition* for identification.

To motivate the rank and order conditions, consider the simultaneous equation model represented in path analytic form shown in Figure 1. Let p be the number of endogenous variables and let q be the number of exogenous variables. We can write this model as

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} 0 & \beta_{12} \\ \beta_{21} & 0 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} + \begin{bmatrix} \gamma_{11} & \gamma_{12} & 0 \\ 0 & 0 & \gamma_{23} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} + \begin{bmatrix} \zeta_1 \\ \zeta_2 \end{bmatrix}. \quad (3)$$

In this example, $p = 2$ and $q = 3$. As a useful device for assessing the rank and order condition, we can

Figure 1 Prototype nonrecursive path model

arrange the structural coefficients in a partitioned matrix A of dimension $p \times s$ as

$$\begin{aligned} \mathbf{A} &= [(\mathbf{I} - \mathbf{B}) | -\Gamma], \\ &= \begin{bmatrix} 1 & -\beta_{12} & -\gamma_{11} & -\gamma_{12} & 0 \\ -\beta_{21} & 1 & 0 & 0 & -\gamma_{23} \end{bmatrix}, \end{aligned} \quad (4)$$

where $s = p + q$. Note that the zeros placed in (4) represent paths that have been excluded (restricted) from the model based on *a priori* model specification. We can represent the restrictions in the first equation of A , say A_1 , as $A_1\phi_1 = 0$, where ϕ_1 is a column vector whose h th element ($h = 1, \dots, s$) is unity and the remaining elements are zero. Thus, ϕ_1 selects the particular element of A_1 for restriction. A similar equality can be formed for A_2 , the second equation in the system. The rank condition states that a necessary and sufficient condition for the identifiability of the first equation is that the rank of $A\phi_1$ must be at least equal to $p - 1$. Similarly for the second equation. The proof of the rank condition is given in [2]. If the rank is less than $p - 1$, then the parameters of the equation are not identified. If the rank is exactly equal to $p - 1$, then the parameters of the equation in question are just identified. If the rank is greater than $p - 1$, then the parameters of the equation are overidentified.

The rank condition can be easily implemented as follows. Delete the columns containing nonzero elements in the row corresponding to the equation of interest. Next, check the rank of the resulting submatrix. If the rank is $p - 1$, then the equation is identified. To take the above example, consider the identification status of the first equation. Recall that for this example, $p - 1 = 1$. According to the procedure just described, the resulting submatrix is

$$\begin{bmatrix} 0 \\ -\gamma_{23} \end{bmatrix}.$$

With the first row zero, the rank of this matrix is one, and, hence, the first equation is identified. Considering the second equation, the resulting submatrix is

$$\begin{bmatrix} -\gamma_{11} & -\gamma_{12} \\ 0 & 0 \end{bmatrix}.$$

Again, because of the zeros in the second row, the rank of this submatrix is 1 and we conclude that the second equation is identified.

A corollary of the rank condition is referred to as the *order condition*. The order condition states that the number of variables (exogenous and endogenous) excluded (restricted) from any of the equations in the model must be at least $p - 1$ [2]. Despite the simplicity of the order condition, it is only a necessary condition for the identification of an equation of the model. Thus, the order condition guarantees that there is a solution to the equation, but it does not guarantee that the solution is unique. A unique solution is guaranteed by the rank condition.

As an example of the order condition, we observe that the first equation has one restriction and the second equation has two restrictions as required by the condition that the number of restrictions must be at least $p - 1$ (here, equal to one). It may be of interest to modify the model slightly to demonstrate how the first equation of the model would not be identified according to the order condition. Referring to Figure 1, imagine a path from x_3 to y_1 . Then the zero in the first row of A would be replaced by $-\gamma_{13}$. Using the simple approach for determining the order condition, we find that there are no restrictions in the first equation and, therefore, the first equation is not identified. Similarly, the first equation fails the rank condition of identification.

This chapter considered identification for recursive and nonrecursive simultaneous equation models. A much more detailed exposition of identification can be found in [2]. It should be pointed out that the above discussion of identification is model-specific and the data play no role. Problems of identification can arise from specific aspects of the data. This is referred to as *empirical identification* and the problem is most closely associated with issues of colinearity.

Briefly, consider a simple linear regression model

$$y = \beta_1 x_1 + \beta_2 x_2 + \zeta. \quad (5)$$

If x_1 and x_2 were perfectly collinear, then $x_1 = x_2 = x$, and equation (5) can be rewritten as

$$\begin{aligned} y &= \beta_1 x + \beta_2 x + \zeta, \\ &= (\beta_1 + \beta_2)x + \zeta. \end{aligned} \quad (6)$$

It can be seen from application of the counting rule that (5) is identified, whereas (6) is not. Therefore, the problem of colinearity can induce empirical nonidentification.

Inbred Strain Study

Genetic contributions in complex trait analyses can be controlled or removed by the use of inbred strains as the test subjects. To be regarded as inbred strains, the mammals concerned must have been subjected to at least 20 generations of full-sib mating (the expected inbreeding coefficient will be 98.6% or greater) [1], resulting in near total genetic similarity among strain members. Such levels of inbreeding are most easily achieved with smaller laboratory species such as the mouse. More than 100 inbred strains of mouse are commercially available through the Jackson Laboratories (www.jax.org) alone. Other species (rat, hamster, guinea pig, rabbit, chicken, amphibian, and fish) are less widely represented by commercially available inbred strains.

Variation in the test scores observed within inbred strains will be of either environmental (treatment) origin or otherwise caused by random experimental error, since genetic variation is largely absent. When the same inbred strain is tested across multiple environments or treatments, the source and extent of the environmental effects can be readily ascertained.

The fixed effect of genotype within environment (treatment) can be measured reliably if there is replication of inbred strain and gender within strain when multiple strains are compared.

By combining the resources of strain and treatment in a model in which other environmental variables are controlled, the assessment of genotype by treatment interaction (*see* **Gene-Environment Interaction**) is enabled. The advantage of using different inbred strains over out-bred individuals in such a study is that genotype can be rigorously fitted as a fixed rather than random effect (*see* **Fixed and Random Effects**) in the analysis, and replication within genotype is possible leading to reduced random genetic errors.

Analytical methods commonly applied to the testing of the relative significance of genotypic and treatment effects on behavioural traits include the **analysis of variance** and **multivariate analysis of variance**, **principal component analysis** or principal factor analysis (*see* **Factor Analysis: Exploratory**), **discriminant analysis** (which has now been largely replaced by **logistic regression**), with ANOVA being the most commonly employed analytical method.

The genetic stability of the inbred strains makes them amenable to crossbreeding for Linkage Analysis.

Ascertainment of genetic distinction in measurement between inbred mouse strains can be used to localize regions of the genome responsible for the trait in question using haplotype analysis. Recent studies have shown that many of the commonly used inbred mice share common ancestry over around 67% of their genomes in any pairwise comparison of strains [2]. Should this commonality of ancestry be generally true and should the ancestral regions be randomly placed, then, as more inbred strains are observed for the trait, the genomic regions that fit the phenotypic results for all strains would be reduced in size. Simple observation of inbred strain phenotype in combination with knowledge of ancestral haplotype might reduce the search space for an inferred genomic region by a substantial proportion. This method is most easily applied when a broad region of likelihood of causation is first identified by either linkage analysis or a genome-wide SNP scan. For accurate resolution, SNPs need to be ultimately observed at intervals of 50 kilobases or less. The method is applicable in the inbred mouse because of the nature of its breeding history and is unlikely to be applicable to other inbred species at this time.

Example

To ascertain whether behavioral test standardization was sufficient to prevent inter-laboratory differences in the results of behavioral testing in mice, Wahlsten et al. [3], studied the impact of three laboratory environments on six behavioral test results in the mouse. Testing four mice from each of eight strains, two sexes, and two shipping conditions (locally bred or shipped), 128 mice per laboratory were tested. Factorial analysis of variance (ANOVA) (*see* **Factorial Designs**) was used in the final analysis of the data. Degrees of freedom for individual effects are simply $(g-1)$, where g is the number of genotypes and $(s-1)$, where s is the number of sites (laboratories) tested. The interaction (genotype by site) degrees of freedom is the product of the degrees of freedom for each contributing main effect.

The Table 1 below gives the omega-squared (ω^2) values (*see* **Effect Size Measures**) for three of treatment effects analyzed (that is, those pertaining

2 Inbred Strain Study

Table 1 Results of ANOVA for the elevated plus maze

Variable	<i>N</i>	Genotype (<i>df</i> = 7)	Site (<i>df</i> = 2)	Genotype × site (<i>df</i> = 14)	Multiple <i>R</i> ²
Time in center	379	0.302	0.180	0.134	0.523
Total arms entries	379	0.389	0.327	0.217	0.660
Percent time in open arms	379	0.050 ^a	0.265	N.S.	0.445

^a $p < .01$; all other effects significant at $p < .001$. N.S. indicates $p > .01$.

Values for specific effects are partial omega-squared coefficients.

to the Elevated Plus Maze). Omega-squared is an estimate of the dependent variance accounted for by the independent variable in the population for a fixed effects model, and so is a measure of the importance of that treatment effect in relation to all effects in the model.

$$\omega^2 = \frac{(SS_{\text{effect}} - (DF_{\text{effect}})(MS_{\text{error}}))}{MS_{\text{error}} + SS_{\text{total}}} \quad (1)$$

where SS is the Sum of Squares, DF is the degrees of freedom and MS is the measured Mean Square (SS/DF).

The multiple R-squared (R^2) (see **Multiple Linear Regression**) describes the proportion of all variance accounted for by the corrected model. It is calculated as the sum of squares for the fitted model divided by the total sum of squares.

The researchers concluded that, while there were significant interactions between laboratories and genotypes for the observed effects, the magnitude of the interactions depended upon the measurements in question. The results suggested that test standardization alone is unlikely to completely overcome the influences of different laboratory environments. Most of the larger differences between

inbred strains were able to be successfully replicated across the labs in the study, though strain differences of moderate effects size were less likely to be resolved.

Incidence

Incidence is defined as the number of new cases of a disease in a population at a specified interval of time. For instance, the incidence rate per 1000 is calculated as:

$$1000 \left(\frac{\text{Number of new cases beginning during a defined period of time}}{\text{Averaged number in a defined population exposed to risk during that time}} \right)$$

Cumulative incidence refers to the proportion of the population becoming diseased during a specified period of time. Just like **prevalence** rates, incidence rates can be studied in general or in clinical populations. They are useful morbidity rates that can be considered as baseline data or base rates in case they are derived from a general population study. For instance, one can calculate the incidence of new cases of influenza, tuberculosis, or AIDS per 100 000 individuals per year. Studying the incidence of diseases is a main aim of epidemiology [3, 4]. In psychiatry and behavioral science, incidence refers to the number of newly appearing mental disorders (e.g., schizophrenia) or behavioral problems (e.g., hyperactivity) during a certain time period (e.g., a month, a year). It is very difficult to compute incidence rates of mental disorders or behavioral problems, since often it is unclear when symptoms appeared for the first time. For this reason, most epidemiological studies in psychiatry and behavioral science present period prevalence rates – for instance, the studies by Verhulst [6] on childhood psychopathology in the Netherlands, and the Epidemiological Catchment Area Study [5] and the National Comorbidity Survey [1], both conducted in the United States.

There is a dynamic relationship between prevalence and incidence. This relationship can be presented as follows:

$$\begin{aligned} \text{Point prevalence rate} &= \text{Incidence rate} \\ &\times \text{Average duration} \end{aligned} \quad (1)$$

Underlying this formula is the assumption that the average duration of a disease and the incidence are both fairly stable over time. If this is not the case, the relationship becomes much more complex [3, 4].

An incidence study allows the measurement of the rate at which new cases are added to the population of individuals with a certain disease. It is also possible to examine how a disease develops in a population, to check differences in development between populations and between time periods, and to examine the influence of etiological factors. Incidence studies are to be preferred over prevalence studies if one is interested to identify individuals at risk for a disease or risk factors, since prevalence rates are determined by the incidence and the duration of a disease [2]. Treatment characteristics, preventive measures, and factors affecting mortality may affect the duration of a disease or a problem, and so indirectly influence prevalence rates.

Incomplete Contingency Tables

Whether by design or accident, there may be no observations in one or more cells of a **contingency table**. We refer to such contingency tables as *incomplete* and the data as *sparse*. We can distinguish between two situations in which incomplete tables can be expected [12]:

1. *Structural zeros*. On the basis of our knowledge of the population, we do *not* expect one or more combinations of the factor levels to be observed in a sample. By design, we have one or more empty cells.
2. *Sampling zeros*. Although in the population all possible combinations of factor levels occur, we do not observe one or more of these combinations in our sample. By accident, we have one or more empty cells.

While sampling zeros occur from deficient sample sizes, too many factors, or too many factor levels, structural zeros occur when it is theoretically impossible for a cell to have any observations. For example, let us assume we have two factors, sex (*male, female*) and breast cancer (*yes, no*). While it is medically possible to have observations in the cell representing males who have breast cancer (*male × yes*), the rareness of males who have breast cancer in the population may result in no such cases appearing in our sample. On the other hand, let us say we sample both sex and the frequency of different types of cancers. While the cell representing males who have prostate cancer will have observations, it is impossible to have any observations in the cell representing females who have prostate cancer. Sampling and structural zeros should not be analytically treated the same. While sampling zeros should contribute to the estimation of the model parameters, structural zeros should not.

Invariably, the presence of structural zeros will directly prevent the estimation of certain parameters. Thus, one consequence of fitting **loglinear models** with structural zeros is the necessity for correcting the model degrees of freedom to accurately reflect the number of cells contributing to the analysis and the actual number of parameters estimated

from these cells, not only those representing theoretically impossible combinations (e.g., females with prostate cancer) but also those indirectly preventing the estimation. Typically, ensuring that the degrees of freedom of the model is correct is the most serious problem caused by structural zeros.

In contrast, fitting loglinear models to tables with sampling zeros can be more problematic, because of the infinite parameter estimates that may arise if the tables have margins with zero entries. In addition, the failure to satisfy the large sample assumptions may mean that the actual null distributions of the generalized likelihood ratio (G^2) or the chi-squared (χ^2) test approximations to the true chi-squared (X^2) distribution are far from the intended asymptotic approximations, leading to mistakes in model selection. Owing to inaccuracies in their approximation, G^2 and χ^2 used as goodness-of-fit statistics can mislead as to which of a series of hierarchically nested models is best. Several investigators (e.g., [2, 3, 5, 6], and [8]) have studied the effects of empty cells on G^2 and χ^2 . The basic findings may be summarized as follows: (a) the correctness of the approximations is largely a function of the ratio n/N , where n = the number of cells and N = the total sample size, (b) as n/N becomes smaller, the approximations become less accurate, and (c) the chi-squared approximation to χ^2 is more valid than G^2 for testing models when n/N is small, particularly when $n/N < 5$. However, the maximum value of n/N that is permissible for G^2 and χ^2 to be accurate approximations undoubtedly varies from situation to situation.

If in a particular case n/N is judged too large, there are various strategies available to ameliorate the situation. If sensible theoretically to do so, a simple but often effective strategy is to combine categories together to prevent a cell from having no observations. Exact methods (see **Exact Methods for Categorical Data**) can also be used if the loglinear model is not too large, obviating the need for approximations to X^2 altogether [7, 11]. When exact methods are not feasible, resampling methods such as **bootstrapping** can provide a good approximation to exact distributions [10]. In addition, test statistics from asymptotic approximations that are more accurate when n/N is small can be used instead of the traditional G^2 and χ^2 approximations [4]. Some test statistics are based on refinements to G^2 and χ^2 , whereas others are entirely new, such as the power divergence statistics (λ) introduced by Read and Cressie [9].

2 Incomplete Contingency Tables

One strategy that is often used inadvisably is to add a small constant, such as $1/2$, to cells counts – previously empty cells are no longer empty. The problem with this strategy is that it tends to increase the apparent equality of the cells' frequencies, resulting in a loss of **power** for finding significant effects. If the strategy of adding a constant is adopted, an extremely small constant should be used, much smaller than $1/2$. Agresti [1] recommends a constant on the order of 10^{-8} . He also recommends conducting a **sensitivity analysis** in which the analysis is repeated using different constants, in order to evaluate the relative effects of the constants on parameter estimation and model testing.

Incompleteness of Probability Models

This article concerns the claim that probabilities cannot take account of everything that could be relevant to a particular uncertainty. It has implications for the extent to which probabilities can set standards for people's judgments and for theories concerning the nature of probability. These issues are dealt with in (see **Probability: Foundations of**).

Aristotle held that what we take to be the likelihood of an event occurring depends both on the frequency of occurrence of the type of event we take it to be, and on how representative it is of that sort of event. '... if the thing in question *both* happens *oftener* as we represent it *and* happens more *as* we represent it, the probability is particularly great' [12, p. 1402a]. Thus Aristotle supposed that an event's likelihood is related to how it is represented. Probabilities operate in the same way. A probability describes the uncertainty of an occasion where one of a number of mutually exclusive types of outcome may occur. Where a probability is assigned a value, someone has had to define the outcome types and determine the probability value or at least the means of determining that value. The assignment may seem obvious in games of chance, but even here there are possibilities of bias, cheating, or player incompetence that could be taken into account. However, most uncertainties do not relate to explicit games of chance, and here the assignment of probabilities is more obviously subjective.

The inherent subjectivity in the origins of probabilities means that probabilities are less than ideal because they take no account of self-referential uncertainty. The problem arises because a probability is a description of an uncertainty, and there is always uncertainty about the accuracy of any description that the description itself does not incorporate. Both **Fisher** [5] and Reichenbach [11] postulated complex systems of hierarchical probabilities to deal with this problem. However, although the uncertainty associated with a probability distribution can be addressed by postulating a higher-order probability distribution, there is uncertainty associated with the new characterization of uncertainty, and so an unlimited number of higher-order probability

distributions could be postulated without the problem being resolved.

A second limitation of probability models is that the outcomes they model are either finite or involve continuous variables that can be approximated by finite models to whatever accuracy is desired. States of the world are more complex than this. Cantor showed that there are many higher-order infinities of possibilities that can be imagined. In particular, there is more than a single infinity of points in a continuum [8]. It follows that probability models are not complex enough to capture the uncertainty regarding an outcome that lies at a point on a continuum, and there is no reason why outcomes should not be more complex, for example, the shape of an object (see [10] for the complexities of specifying the outline of an object). Probability models cannot conceivably incorporate all the possible distinctions between what might be regarded as outcomes, let alone characterize the uncertainties associated with all distinguishable outcomes [9].

Lest the above comments be seen to be mere mathematical technicalities that in practice can be ignored, it is worth thinking about the problem psychologically. What people perceive as happenings in the world have more substance and are less well-defined than the events in probability models. Consider a murder – what constitutes the event of the killing? When does it start – with the planning, the acquiring of the means, the execution of the act of murder, or when the victim is fatally injured? Where does it take place – where the murderer is, where the victim is, or both, and does it move as the killing takes place, for example, does it follow the mortally wounded victim until death occurs? There is even an issue about exactly when a person dies [14]. A little thought shows that events that take place in people's lives (births, deaths, marriages, etc.) do not occur instantaneously. They take place over time and space and can be incorporated into larger events or broken down into component events without any apparent limit. A complete characterization of the uncertainty associated with a particular happening would seem to require that the happening itself be fully specified, yet such a specification seems inconceivable. To apply a probability model, there has to be a limit to the distinctions that can be made between events. Happenings characterized by probabilities cannot be extended or broken down to an unlimited extent. Anscombe [2] put it nicely when

2 Incompleteness of Probability Models

she said that events have to be ‘cut and dried’ in order to be assigned probabilities. Because of this, a probability may always be improved by making more distinctions between events regardless of however well an associated probability model may appear to be consistent with the available evidence.

Fisher [4] considered what an ideal probability model would be like starting with a ‘cut and dried’ outcome. Such a model would classify events into sets containing no identifiable subsets – that is to say, sets that could not be further broken down into subsets where the outcome in question was associated with different probabilities. This involves postulating sets of equivalent or exchangeable events, which is how **de Finetti** conceived of ideal probability models [3]. Probabilities assigned to events in such sets could not be improved on by taking additional variables into account. Such probabilities are important as the laws of large numbers ensure that, in this case, each probability has a ‘correct’ value – the limit of the relative frequency of equivalent events as n increases. Betting that one of the equivalent events will occur taking the odds to be $p:(1-p)$, where p is this ‘correct’ probability, will do better than any other value over the long term (Dutch book theorem: [7]). Unfortunately, one can never know that any two events are equivalent let alone that any set of events has no identifiable subsets.

If all the uncertainty concerning happenings in the world could be captured by a probability, then it would have a correct value, and optimal solutions to probability problems regarding real-life events would exist. As things stand, however, probabilities regarding real-life events are based on analogies between the uncertainties in the world and models originating in people’s heads. Furthermore, probability models do not explain how these analogies come to be formed [13]. As Aristotle foresaw around 2000 years before probability was invented, what probability should be assigned to an event depends on how it is characterized, and that is a matter for reasoned argument. Inferences from probabilities, be they relative frequencies, estimates of people’s beliefs, the P values in statistical tests, or posterior probabilities in **Bayesian statistics** are necessarily subject to revision when it is argued that the events being modeled should be characterized in more detail or that

the probability models should be modified to take account of possibilities their inventors had not foreseen. Unforeseen occurrences can also pose problems for theories that suppose that probabilities are the limits of relative frequencies because the relative frequency of events that have never occurred is zero, but clearly novel events occur [6]. Probabilities and their interpretation should be seen as matters for debate rather than as the necessary consequences of applying the correct analysis to a particular problem [1].

Independence: Chi-square and Likelihood Ratio Tests

The simplest and most common test of independence is the chi-square test. It is a *nonparametric* test of significance that is used to analyze *categorical variables*. Categorical variables can often be on a nominal scale, indicating that the categories may have no ordering. Chi-square tests of independence can therefore be applied to a very broad range of data, qualitative as well as quantitative, anything that one can categorize and count (*see Contingency Tables; Goodness of Fit for Categorical Variables*).

Suppose that occupational data and musical preference data are gathered from a random sample of 1292 citizens of an Alaskan community. For each respondent, the data will consist of two qualitative categories, one for occupation and one for musical preference data. The primary qualitative data could look like this:

Respondent 1: lumberjack, preference for The Eagles
Respondent 2: merchant, preference for Led Zeppelin
Respondent 3: lumberjack, preference for Led Zeppelin
Respondent 4: fisherman, preference for Jethro Tull
Respondent 5: fisherman, preference for Led Zeppelin.

Data of this kind for all 1292 respondents can be collected into a **contingency table**, as shown below in Table 1:

These data are *frequency* data – they indicate how frequently each combination of categories in the 3×3 table occurs. The chi-square test of independence may be used to analyze this contingency table to determine whether there is a relationship between occupation and musical preference. The null

hypothesis holds that the two are not related – that they are independent.

The Chi-square Test of Independence

The 3×3 contingency table given above for the occupation and musical preference study (minus the row and column marginal totals) is the *observed* frequency matrix, symbolized as O :

$$O = \begin{bmatrix} 230 & 246 & 9 \\ 130 & 478 & 47 \\ 15 & 83 & 54 \end{bmatrix} \quad (1)$$

The matrix of expected values (the frequency values that would be expected if the two variables of occupation and musical preference were independent) is found by obtaining the product of the *row marginal total* and the *column marginal total* corresponding to each cell, and dividing this product by the *grand total*. This is done for each cell as shown below:

$$E = \begin{bmatrix} \left(\frac{485 \times 375}{1292}\right) & \left(\frac{485 \times 807}{1292}\right) & \left(\frac{485 \times 110}{1292}\right) \\ \left(\frac{655 \times 375}{1292}\right) & \left(\frac{655 \times 807}{1292}\right) & \left(\frac{655 \times 110}{1292}\right) \\ \left(\frac{152 \times 375}{1292}\right) & \left(\frac{152 \times 807}{1292}\right) & \left(\frac{152 \times 110}{1292}\right) \end{bmatrix} \\ = \begin{bmatrix} 140.77 & 302.94 & 41.29 \\ 190.11 & 409.12 & 55.77 \\ 44.12 & 94.94 & 12.94 \end{bmatrix} \quad (2)$$

The *observed minus expected* matrix is

$$O - E = \begin{bmatrix} 89.23 & -56.94 & -32.29 \\ -60.11 & 68.88 & -8.77 \\ -29.12 & -11.94 & 41.06 \end{bmatrix} \quad (3)$$

The fundamental equation for chi-square is to obtain the *squared difference between the observed value (O) and the corresponding expected value (E)*,

Table 1 Contingency table relating musical preference to occupation

	The Eagles	Led Zeppelin	Jethro Tull	Row totals
Lumberjacks	230	246	9	485
Fishermen	130	478	47	655
Merchants	15	83	54	152
Column totals	375	807	110	1292

2 Independence: Chi-square and Likelihood Ratio Tests

divided by the expected value (E) for each cell, and then to sum all of these:

$$\begin{aligned}\chi^2 &= \sum \frac{(O - E)^2}{E} \\ &= \frac{89.23^2}{140.77} + \frac{(-56.94)^2}{302.94} + \frac{(-32.29)^2}{41.29} \\ &\quad + \frac{(-60.11)^2}{190.11} + \frac{68.88^2}{409.12} + \frac{(-8.77)^2}{55.77} \\ &\quad + \frac{(-29.12)^2}{44.12} + \frac{(-11.94)^2}{94.94} + \frac{41.06^2}{12.94} \\ &= 275.48\end{aligned}\quad (4)$$

The degrees of freedom value for this chi-square test is the product $(R - 1) \times (C - 1)$, where R is the number of rows in the contingency table and C is the number of columns. For this 3×3 contingency table $(R - 1) \times (C - 1) = (3 - 1) \times (3 - 1) = 4$ df. In a table of critical values for the chi-square distribution, the value needed to reject the null hypothesis at the 0.001 level for 4 degrees of freedom is found to be 18.467. The obtained value of 275.48 exceeds this, so the null hypothesis of independence can be rejected at the 0.001 level. That is, these data give substantial evidence that occupation and musical preference are systematically related, and therefore not independent. Although this example is for a 3×3 contingency table, the chi-square test of independence may be used for two-way tables with any number of rows and any number of columns.

Expanding Chi-square to Other Kinds of Hypotheses

Other chi-square tests are possible besides the test of independence. Suppose in the example just given that the 1292 respondents were a random sample of workers in a particular Alaskan city, and that you wish to test workers' relative preferences for these three musical groups. In other words, you wish to test the null hypothesis that workers in the population from which this random sample is obtained are equally distributed in their preferences for the three musical groups. The *observed* (O) matrix is the column marginal totals:

$$O = [375 \quad 807 \quad 110] \quad (5)$$

The null hypothesis in this case is that the three column categories have equal frequencies in the population, so the *expected* (E) matrix consists of the total 1292 divided by 3 (which gives 430.67), with this entry in each of the three positions. The $O - E$ matrix is therefore

$$\begin{aligned}O - E &= [375 \ 807 \ 110] - [430.67 \ 430.67 \ 430.67] \\ &= [-55.67 \ 376.33 \ -320.67]\end{aligned}\quad (6)$$

The obtained chi-square statistic is

$$\chi_{\text{columns}}^2 = \sum \frac{(O - E)^2}{E} = 574.81 \quad (7)$$

This chi-square test has 2 degrees of freedom, three columns minus one ($C - 1$), for which the critical ratio at the 0.001 level is 13.816. The null hypothesis of equal preferences for the three groups can therefore be rejected at the 0.001 level.

So far, two chi-square statistics have been calculated on this set of data, a test of independence and a test of equality of proportions across columns (musical preference). The third chi-square test to be computed is the test for row effects (occupation). The *observed* (O) matrix is the row marginal totals:

$$O = \begin{bmatrix} 485 \\ 655 \\ 152 \end{bmatrix} \quad (8)$$

The null hypothesis in this case is that the three row categories (occupations) have equal frequencies within the population. Therefore, the *expected* (E) matrix consists of the total 1292 divided by 3 (which gives 430.67), with this same entry in each of the three positions. The obtained chi-square statistic is

$$\chi_{\text{rows}}^2 = \sum \frac{(O - E)^2}{E} = 304.01 \quad (9)$$

With 2 degrees of freedom, the critical ratio for significance at the 0.001 level is 13.816, so the null hypothesis of equal occupational distribution can be rejected at the 0.001 level.

The fourth and final chi-square statistic to be computed is that for the total matrix. The *observed* (O) matrix is again the 3×3 matrix of observed frequencies, just as it was for the $R \times C$ test of independence given above. However, even though the observed matrix is the same, the null hypothesis (and therefore the expected matrix) is very different.

This test is an omnibus test of whether there is any significance in the matrix considered as a whole (row, column, or $R \times C$ interaction), and the null hypothesis is therefore the hypothesis that all of the cells are equal. All nine entries in the *expected* (E) matrix are 143.56, which is one-ninth of 1292. The $O - E$ matrix is therefore

$$\begin{aligned} O - E &= \begin{bmatrix} 230 & 246 & 9 \\ 130 & 478 & 47 \\ 15 & 83 & 54 \end{bmatrix} \\ &\quad - \begin{bmatrix} 143.56 & 143.56 & 143.56 \\ 143.56 & 143.56 & 143.56 \\ 143.56 & 143.56 & 143.56 \end{bmatrix} \\ &= \begin{bmatrix} 86.44 & 102.44 & -134.56 \\ -13.56 & 334.44 & -96.56 \\ -128.56 & -60.56 & -89.56 \end{bmatrix} \quad (10) \end{aligned}$$

The obtained chi-square statistic is

$$\chi_{\text{total}}^2 = \sum \frac{(O - E)^2}{E} = 1293.20 \quad (11)$$

This chi-square has 8 degrees of freedom, the total number of cells minus one ($RC - 1$), with a critical ratio, at the 0.001 level, of 26.125. The null hypothesis of no differences of any kind within the entire data matrix can therefore be rejected at the 0.001 level.

These four kinds of information can be obtained from a contingency table using chi-square. However, there is a problem in using chi-square in this way. The total analysis should have a value that is equal to the sum of the other three analyses that make it up. The values should be additive, but this is not the case as shown with the example data:

$$\begin{aligned} \chi_{\text{total}}^2 &= 1293.20 \neq 1154.30 \\ &= 304.01 + 574.81 + 275.48 \\ &= \chi_{\text{rows}}^2 + \chi_{\text{columns}}^2 + \chi_{R \times C}^2 \quad (12) \end{aligned}$$

As will be shown in the next section, this additivity property *does* hold for the likelihood ratio G^2 statistic of log-linear analysis. Log-linear analysis is supported by a more coherent mathematical theory than chi-square that enables this additivity property to hold, and also enables one to use the full power of linear models applied to categorical data (see **Log-linear Models**).

Multiplicative Models, Additive Models, and the Rationale for Log-linear

The procedure given above for obtaining the matrix of expected frequencies is a direct application of the *multiplication rule of probabilities for independent joint events*:

$$P(A \text{ and } B) = P(A) \times P(B) \quad (13)$$

For example, for the Alaskan sample described above, the probability of a respondent being a lumberjack is

$$P(A) = \frac{\text{frequency of lumberjacks}}{\text{total frequency}} = \frac{485}{1292} = 0.375 \quad (14)$$

Similarly, the probability of a respondent preferring Jethro Tull music is

$$\begin{aligned} P(B) &= \frac{\text{frequency of Jethro Tull preference}}{\text{total frequency}} \\ &= \frac{110}{1292} = 0.085 \quad (15) \end{aligned}$$

If these two characteristics were independent of one another, the joint probability of a respondent being a lumberjack *and* also preferring Jethro Tull music would (by the multiplication rule for joint events) be

$$\begin{aligned} P(A \text{ and } B) &= P(A) \times P(B) \\ &= (0.375) \cdot (0.085) = 0.032 \quad (16) \end{aligned}$$

Multiplying this probability by 1292, the number in the sample, gives 41.3, which is (to one decimal place) the value of the expected frequency of the lumberjack/Jethro Tull cell.

Interaction terms in **analysis of variance** (ANOVA) use a similar kind of ‘observed minus expected’ logic and an analogous method for obtaining expected values. The simple definitional formula for the sum of squares of a two-way interaction is

$$\begin{aligned} SS(AB) &= n \sum \sum (\bar{X}_{ab} - \bar{X}_{a.} - \bar{X}_{.b} + \bar{X}_{..})^2 \\ &= n \sum \sum (\bar{X}_{ab} - \bar{E}_{ab})^2 \quad (17) \end{aligned}$$

This sum can be decomposed as the multiplicative factor n (cell frequency) times the ‘sum of squared

4 Independence: Chi-square and Likelihood Ratio Tests

deviations from additivity', where 'deviations from additivity' refers to the deviations of the observed means (O) from the expected means (E), those that would be expected if an additive model were true. This is because the additive model for creating means is given by

$$\bar{E}_{ab} = \bar{X}_{a.} + \bar{X}_{.b} - \bar{X}_{..} \quad (18)$$

The two processes are analogous. To obtain the expected cell means for ANOVA, one sums the marginal row mean and the marginal column mean and subtracts the grand mean. To obtain expected cell frequencies in a contingency table, one multiplies marginal row frequencies by marginal column frequencies and divides by the total frequency. By taking logarithms of the frequency values, one converts the multiplicative computations of contingency table expected values into the additive computations of ANOVA, thus making frequency data amenable to linear models analysis. This log-linear approach comes with a number of advantages: it enables one to test three-way and higher contingency tables, to additively decompose test statistics, and in general to apply powerful general linear models analysis to categorical data. The log-linear model will be briefly demonstrated for two-way tables.

Log-linear Models

The observed and expected matrices for each of the four tests demonstrated above are the same for log-linear analysis as for the chi-square analysis. All that differs is the formula for calculating the likelihood ratio statistic G^2 . It is given as two times the sum over all the cells of the following quantity: *the observed value times the natural logarithm of the ratio of the observed value to the expected value*.

$$G^2_{\text{total}} = 2 \sum O \log_e \left(\frac{O}{E} \right) \quad (19)$$

Four likelihood ratio statistics will be demonstrated, corresponding to the four chi-square statistics just calculated. The first is the test of the row by column interaction. This is called *the likelihood ratio test for independence*. The likelihood ratio statistic for this test (using O and E values obtained above) is calculated as

$$G^2_{RC} = 2 \sum O \log_e \left(\frac{O}{E} \right)$$

$$= 2 \times \left[\begin{aligned} &230 \times \log_e \left(\frac{230}{140.77} \right) \\ &+ 246 \times \log_e \left(\frac{246}{302.94} \right) \\ &+ 9 \times \log_e \left(\frac{9}{41.29} \right) \\ &+ 130 \times \log_e \left(\frac{130}{190.11} \right) \\ &+ 478 \times \log_e \left(\frac{478}{409.12} \right) \\ &+ 47 \times \log_e \left(\frac{47}{55.77} \right) \\ &+ 15 \times \log_e \left(\frac{15}{44.12} \right) \\ &+ 83 \times \log_e \left(\frac{83}{94.94} \right) \\ &+ 54 \times \log_e \left(\frac{54}{12.94} \right) \end{aligned} \right] \quad (20)$$

$$= 229.45$$

This likelihood ratio has the same degrees of freedom as the corresponding chi-square, $(R - 1) \times (C - 1) = 4$, and it is also looked up in an ordinary chi-square table. The critical ratio for significance at the 0.001 level with 4 degrees of freedom is 18.467. The null hypothesis of independence can therefore be rejected at the 0.001 level.

The likelihood ratio statistic for rows is

$$\begin{aligned} G^2_{\text{rows}} &= 2 \sum O \log_e \left(\frac{O}{E} \right) \\ &= 2 \times \left[\begin{aligned} &485 \times \log_e \left(\frac{485}{430.67} \right) \\ &+ 655 \times \log_e \left(\frac{655}{430.67} \right) \\ &+ 152 \times \log_e \left(\frac{152}{430.67} \right) \end{aligned} \right] \\ &= 347.93 \end{aligned} \quad (21)$$

This test has a 0.001 critical ratio of 13.816 with $2(R - 1)$ degrees of freedom, so the null hypothesis can be rejected at the 0.001 level.

The third likelihood ratio statistic to be calculated is that for columns:

$$G^2_{\text{columns}} = 2 \sum O \log_e \left(\frac{O}{E} \right) = 609.50 \quad (22)$$

which is also significant at the 0.001 level.

The likelihood ratio for the total matrix is

$$G^2_{\text{total}} = 2 \sum O \log_e \left(\frac{O}{E} \right) = 1186.88 \quad (23)$$

With 8 degrees of freedom and a critical ratio of 26.125, this test is also significant at the 0.001 level.

The additivity property holds with these four likelihood ratio statistics. That is, the sum of the obtained G^2 values for rows, columns, and $R \times C$ interaction is equal to the obtained G^2 value for the total matrix:

$$\begin{aligned} G^2_{\text{total}} &= 1186.88 = 347.93 + 609.50 + 229.45 \\ &= G^2_{\text{rows}} + G^2_{\text{columns}} + G^2_{R \times C} \end{aligned} \quad (24)$$

The history of log-linear models for categorical data is given by Imrey, Koch, and Stokes [3], and detailed accounts of the mathematical development are given by Agresti [1], and by Imrey, Koch, and Stokes [4]. Marascuilo and Levin [6] give a particularly readable account of how the logarithmic transformation enables one to analyze categorical data with the general linear model, and Brown, Hendrix, and Hendrix [2] demonstrate the convergence of chi-square and ANOVA through log-linear models with simplest case data.

The calculations involved in both the chi-square analysis and also the log-linear analysis are simple enough to be easily accomplished using a spreadsheet, such as Microsoft Excel, Quattro Pro, ClarisWorks, and so on. They can also be accomplished

using computer statistical packages such as SPSS and SAS. Chi-square analysis can be accomplished using the FREQ procedure of SAS, and log-linear analysis can be accomplished in SAS using CATMOD (see **Software for Statistical Analyses**). Landau and Everitt [5] demonstrates (in Chapter 3) how to use SPSS to do chi-square analysis and also how to do cross-tabulation of categorical and continuous data.

Independent Component Analysis

Introduction

‘I shouldn’t be surprised if it hailed a good deal tomorrow’, Eeyore was saying ... ‘Being fine to-day doesn’t Mean Anything. It has no sig – what’s that word? Well, it has none of that.’

– The House at Pooh Corner, AA Milne, 1928.

Most measured quantities are actually mixtures of other quantities. Typical examples are (a) sound signals in a room with several people talking simultaneously, (b) an electroencephalogram (EEG) signal, which contains contributions from many different brain regions, and (c) a person’s height, which is determined by contributions from many different genetic and environmental factors. Science is, to a large extent, concerned with establishing the precise nature of the component processes responsible for a given set of measured quantities, whether these involve height, EEG signals, or even IQ. Under certain conditions, the signals underlying measured quantities can be recovered by making use of ICA. ICA is a member of a class of *blind source separation* (BSS) methods.

The success of ICA depends on one key assumption regarding the nature of the physical world. This assumption is that independent variables or signals¹ are generated by different underlying physical processes. If two signals are independent, then the value of one signal cannot be used to predict anything about the corresponding value of the other signal. As it is not usually possible to measure the output of a single physical process, it follows that most measured signals must be mixtures of independent signals. Given such a set of measured signals (i.e., mixtures), ICA works by finding a transformation of those mixtures, which produces independent signal components, on the assumption that each of these independent component signals is associated with a different physical process. In the language of ICA, the measured signals are known as *signal mixtures*, and the required independent signals are known as *source signals*.

ICA has been applied to separation of different speech signals [1]², analysis of EEG data [6], functional magnetic resonance imaging (fMRI) data [7], image processing [2], and as a model of biological image processing [10].

Before embarking on an account of the mathematical details of ICA, a simple, intuitive example of how ICA could separate two speech signals is given. However, it should be noted that this example could equally well apply to *any physically measured set of signals, and to any number of signals* (e.g., images, biomedical data, or stock prices).

Applying ICA to Speech Data

Consider two people speaking at the same time in a room containing two microphones, as depicted in Figure 1. If each voice signal is examined at a fine time scale, then it is apparent that the amplitude of one voice at any given point in time is unrelated to the amplitude of the other voice at that time. The reason that the amplitudes of two voices are unrelated is that they are generated by two unrelated physical processes (i.e., by two different people). If we know that the voices are unrelated, then one key strategy for

Figure 1 ICA in a nutshell: If two people speak at the same time in a room containing two microphones, then the output of each microphone is a *mixture* of two voice signals. Given these two *signal mixtures*, ICA can recover the two original voices or *source signals*. This example uses speech, but ICA can extract source signals from any set of two or more measured signal mixtures, where each signal mixture is assumed to consist of a linear mixture of source signals (see section ‘Mixing Signals’)

separating voice mixtures (e.g., microphone outputs) into their constituent voice components is to extract unrelated time-varying signals from these mixtures. The property of being unrelated is of fundamental importance.

While it is true that two voice signals are unrelated, this informal notion can be captured in terms of *statistical independence* (see **Probability: An Introduction**), which is often truncated to *independence*. If two or more signals are statistically independent of each other, then the value of one signal provides no information regarding the value of the other signals.

The Number of Sources and Mixtures

One important fact about ICA is often not appreciated. Basically, there must usually be at least as many different mixtures of a set of source signals as there are source signals (but see [9]). For the example of speech signals, this implies that there must be at least as many microphones (different voice mixtures) as there are voices (source signals).

Effects of Mixing Signals

When a set of two or more independent source signals are mixed to make a corresponding set of signal mixtures, as shown in Figure 1, three effects follow.

- *Independence*. Whereas source signals are independent, their signal mixtures are not. This is because each source signal contributes to every mixture, and the mixtures cannot, therefore, be independent.
- *Normality*. The **central limit theorem** ensures that a signal mixture that is the sum of almost any signals yields a bell-shaped, *normal* or *Gaussian* histogram. In contrast, the **histogram** of a typical source signal has a non-Gaussian structure (see Figure 2).
- *Complexity*. The complexity of any mixture is greater than (or equal to) that of its simplest (i.e., least complex) constituent source signal. This ensures that extracting the least complex

Figure 2 Signal mixtures have Gaussian or normal histograms. Signals (top row) and corresponding histograms of signal values (bottom row), where each histogram approximates the *probability density function* (pdf) of one signal. The top panels display only a small segment of the signals used to construct displayed histograms. A speech source signal (a), and a histogram of amplitude values in that signal (d). A sawtooth source signal (b), and its histogram (e). A signal mixture (c), which is the sum of the source signals on the left and middle, and its bell-shaped histogram (f)

signal from a set of signal mixtures yields a source signal [9].

These three effects can be used either on their own or in combination to extract source signals from signal mixtures. The effects labeled *normality* and *complexity* are used in **projection pursuit** [5] and *complexity pursuit* [4, 8], respectively, and the effects labeled *independence* and *normality* are used together in ICA (also see [9]).

Representing Multiple Signals

A speech source signal s_1 is represented as $s_1 = (s_1^1, s_1^2, \dots, s_1^N)$, where s_1 adopts amplitudes s_1^1 , then s_1^2 , and so on; superscripts specify time and subscripts specify signal identity (e.g., speaker identity). We will be considering how to mix and unmix a *set* of two or more signals, and we define a specific set of two time-varying speech signals s_1 and s_2 in order to provide a concrete example. Now, the amplitudes of both signals can be written as a *vector variable* $\mathbf{s}$, which can be rewritten in one of several mathematically equivalent forms:

$$\mathbf{s} = \begin{pmatrix} s_1 \\ s_2 \end{pmatrix} \quad (1)$$

$$= \begin{pmatrix} (s_1^1, s_1^2, \dots, s_1^N) \\ (s_2^1, s_2^2, \dots, s_2^N) \end{pmatrix}. \quad (2)$$

We introduce the transpose operator, which simply transforms rows into columns (or vice versa), and is defined by $\mathbf{s} = (s_1, s_2)^T$.

Mixing Signals

The different distance of each source (i.e., person) from a microphone ensures that each source contributes a different amount to the microphone's output. The microphone's output is, therefore, a *linear* mixture x_1 that consists of a weighted sum of the two source signals $x_1 = as_1 + bs_2$, where the *mixing coefficients* a and b are determined by the distance of each source from each microphone. As we are concerned here with unmixing a set of two signal mixtures (see Figure 1), we need another microphone in a different location from the first. In this case, the microphone's output x_2 is $x_2 = cs_1 + ds_2$, where the mixing coefficients are c and d .

Unmixing Signals

Generating mixtures from source signals in this linear manner ensures that each source signal can be recovered by a linearly recombining signal mixtures. The precise nature of this recombination is determined by a set of *unmixing coefficients* $(\alpha, \beta, \gamma, \delta)$, such that $s_1 = \alpha x_1 + \beta x_2$ and $s_2 = \gamma x_1 + \delta x_2$. Thus, the problem solved by ICA, and by all other BSS methods, consists of finding values for these unmixing coefficients.

The Mixing and Unmixing Matrices

The set of mixtures defines a vector variable $\mathbf{x} = (x_1, x_2)^T$, and the transformation from $\mathbf{s}$ to $\mathbf{x}$ defines a *mixing matrix* $\mathbf{A}$:

$$\begin{aligned} \mathbf{x} &= \begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} s_1^1 & s_1^2 & \dots & s_1^N \\ s_2^1 & s_2^2 & \dots & s_2^N \end{pmatrix} \\ &= \mathbf{A}\mathbf{s}. \end{aligned} \quad (3)$$

The mapping from $\mathbf{x}$ to $\mathbf{s} = (s_1, s_2)^T$ defines an optimal *unmixing matrix* $\mathbf{W}^* = (\mathbf{w}_1, \mathbf{w}_2)^T$ with (row) weight vectors $\mathbf{w}_1^T = (\alpha, \beta)$ and $\mathbf{w}_2^T = (\gamma, \delta)$

$$\begin{aligned} \mathbf{s} &= \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} \begin{pmatrix} x_1^1 & x_1^2 & \dots & x_1^N \\ x_2^1 & x_2^2 & \dots & x_2^N \end{pmatrix} \\ &= (\mathbf{w}_1, \mathbf{w}_2)^T (x_1, x_2) \end{aligned} \quad (4)$$

$$= \mathbf{W}^* \mathbf{x}. \quad (5)$$

It can be seen that $\mathbf{W}^*$ reverses, or inverts, the effects of $\mathbf{A}$, and indeed, $\mathbf{W}^*$ could be estimated from the *matrix inverse* $\mathbf{W}^* = \mathbf{A}^{-1}$, if $\mathbf{A}$ were known³. However, as we are ultimately concerned with finding $\mathbf{W}^*$ when $\mathbf{A}$ is not known, we cannot, therefore, use $\mathbf{A}^{-1}$ to estimate $\mathbf{W}^*$. For arbitrary values of the unmixing coefficients, the unmixing matrix is suboptimal and is denoted $\mathbf{W}$. In this case, the signals extracted by $\mathbf{W}$ are not necessarily source signals, and are denoted $\mathbf{y} = \mathbf{W}\mathbf{x}$.

Maximum Likelihood ICA

In practice, it is extremely difficult to measure the independence of a set of extracted signals unless we

4 Independent Component Analysis

have some general knowledge about those signals. In fact, the observations above suggest that we do often have some knowledge of the source signals. Specifically, we know that they are non-Gaussian, and that they are independent. This knowledge can be specified in terms of a formal model, and we can then extract signals that conform to this model. More specifically, we can search for an unmixing matrix that maximizes the agreement between the model and the signals extracted by that unmixing matrix.

One common interpretation of ICA is as a *maximum likelihood* (ML) method for estimating the optimal unmixing matrix $\mathbf{W}^*$. **Maximum likelihood estimation (MLE)** is a standard statistical tool for finding parameter values (e.g., the unmixing matrix $\mathbf{W}$) that provide the best fit of some data (e.g., the signals $\mathbf{y}$ extracted by $\mathbf{W}$) to a given a model. The ICA ML ‘model’ includes the adjustable parameters in $\mathbf{W}$, and a (usually fixed) model of the source signals. However, this source signal model is quite vague because it is specified only in terms of the general shape of the histogram of source signals. The fact that the model is vague means that we do not have to know very much about the source signals.

As noted above, mixtures of source signals are almost always Gaussian (see Figure 2), and it is fairly safe to assume that non-Gaussian signals must, therefore, be source signals. The amount of ‘Gaussian-ness’ of a signal can be specified in terms of its histogram, which is an approximation to a *probability density function* (pdf) (see Figure 2). A pdf $p_s(s)$ is essentially a histogram in which bin widths Δs are extremely small. The value of the function $p_s(s')$ is the *probability density* of the signal s at the value s' , which is the probability that the signal s lies within a small range around the value⁴ s' . As a pure speech signal contains a high proportion of silence, its pdf is highly ‘peaky’ or *leptokurtotic*, with a peak around zero (see Figure 3). It, therefore, makes sense to specify a leptokurtotic function (see **Kurtosis**) as our model pdf for speech source signals.

As we know the source signals are independent, we need to incorporate this knowledge into our model. The degree of mutual independence between signals can be specified in terms of their *joint pdf* (see Figure 3). By analogy, with the pdf of a scalar signal, a joint pdf defines the probability that the values of a set of signals $\mathbf{s} = (s_1, s_2)^T$ fall within a small range around a specific set of values $\mathbf{s}' = (s'_1, s'_2)^T$. Crucially, if these signals are mutually independent,

Figure 3 Marginal and joint probability density function (pdfs) of two high-kurtosis independent variables (e.g., speech signals). Given a set of signals $\mathbf{s} = (s_1, s_2)^T$, the pdf of each signal is essentially a histogram of values in that signal, as indicated by the two curves plotted along the horizontal axes. Similarly, the joint pdf p_s of two signals is essentially a two-dimensional histogram of pairs of signal values $\mathbf{s}' = (s'_1, s'_2)$ at time t . Accordingly, the joint probability of observing values $\mathbf{s}' = (s'_1, s'_2)$ is indicated by the local density of plotted points on the horizontal plane. This local density is an approximation to the joint pdf p_s , which is indicated by the height of the solid surface. The pdfs p_{s_1} and p_{s_2} of the signals s_1 and s_2 are the *marginal* pdfs of the joint pdf p_s .

then the joint pdf p_s of $\mathbf{s}$ can be expressed as the product of the pdfs (p_{s_1}, p_{s_2}) of its constituent signals s_1 and s_2 . That is, $p_s = p_{s_1} \times p_{s_2}$, where the pdfs p_{s_1} and p_{s_2} of the signals s_1 and s_2 (respectively) are known as the *marginal* pdfs of the joint pdf p_s .

Using ML ICA, the objective is to find an unmixing matrix $\mathbf{W}$ that yields extracted signals $\mathbf{y} = \mathbf{W}\mathbf{x}$, which have a joint pdf as similar as possible to the model joint pdf p_s of the unknown source signals $\mathbf{s}$. This model incorporates the assumptions that source signals are non-Gaussian (leptokurtotic, in the case of speech) and independent. Fortunately, ICA seems to be very robust with respect to differences between model pdfs and the pdfs of source signals [3]. Note that, as $\mathbf{A}$ and $\mathbf{W}$ are inverses of each other⁵, it does not matter whether the model parameters are expressed in terms of $\mathbf{A}$ or $\mathbf{W}$.

Somewhat perversely, we can consider the probability of obtaining the observed mixtures $\mathbf{x}$ in the context of such a model, where this probability is known as the *likelihood* of the mixtures. We can then pose the question: given that the source signals have

a joint pdf p_s , which particular mixing matrix $\mathbf{A}$ (and, therefore, which unmixing matrix $\mathbf{W} = \mathbf{A}^{-1}$) is most likely to have generated the observed signal mixtures $\mathbf{x}$? In other words, if the likelihood of obtaining the observed mixtures (from some unknown source signals with joint pdf p_s) were to vary with $\mathbf{A}$, then which particular $\mathbf{A}$ would maximize this likelihood?

MLE is based on the assumption that if the model joint pdf p_s and the model parameters $\mathbf{A}$ are correct, then a high probability (i.e., likelihood) should be obtained for the mixtures $\mathbf{x}$ that were actually observed. Conversely, if $\mathbf{A}$ is far from the correct parameter values, then a low probability of the observed mixtures would be expected. We will assume that all source signals have the same (leptokurtotic) pdf p_s . This may not seem much to go on, but it turns out to be perfectly adequate for extracting source signals from signal mixtures.

The Nuts and Bolts of ML ICA

Consider a (mixture) vector variable $\mathbf{x}$ with joint pdf p_x , and a (source) vector variable $\mathbf{s}$ with joint pdf p_s , such that $\mathbf{s} = \mathbf{W}^* \mathbf{x}$, where $\mathbf{W}^*$ is the optimal unmixing matrix. As noted above, the number of source signals and mixtures must be equal, which ensures that $\mathbf{W}^*$ is square. In general, the relation between the joint pdfs of $\mathbf{x}$ and $\mathbf{s}$ is

$$p_x(\mathbf{x}) = p_s(\mathbf{s}) |\mathbf{W}^*|, \quad (6)$$

where $|\mathbf{W}^*| = |\partial \mathbf{s} / \partial \mathbf{x}|$ is the *Jacobian* of $\mathbf{s}$ with respect to $\mathbf{x}$. Equation (6) defines the likelihood of the observed mixtures $\mathbf{x}$, which is the probability of $\mathbf{x}$ given $\mathbf{W}^*$.

For any nonoptimal unmixing matrix $\mathbf{W}$, the extracted signals are $\mathbf{y} = \mathbf{W} \mathbf{x}$. Making the dependence on $\mathbf{W}$ explicit, the likelihood $p_x(\mathbf{x}|\mathbf{W})$ of the signal mixtures $\mathbf{x}$ given $\mathbf{W}$ is

$$p_x(\mathbf{x}|\mathbf{W}) = p_s(\mathbf{W} \mathbf{x}) |\mathbf{W}|. \quad (7)$$

We would naturally expect $p_x(\mathbf{x}|\mathbf{W})$ to be maximal if $\mathbf{W} = \mathbf{W}^*$. Thus, (7) can be used to evaluate the quality of any putative unmixing matrix $\mathbf{W}$ in order to find that particular $\mathbf{W}$ that maximizes $p_x(\mathbf{x}|\mathbf{W})$. By convention, (7) defines a *likelihood*

function $L(\mathbf{W})$ of $\mathbf{W}$, and its logarithm defines the *log likelihood function* $\ln L(\mathbf{W})$. If the M source signals are mutually independent, so that the joint pdf p_s is the product of its M marginal pdfs, then (7) can be written

$$\ln L(\mathbf{W}) = \sum_i^M \sum_t^N \ln p_s(\mathbf{w}_i^T \mathbf{x}^t) + N \ln |\mathbf{W}|. \quad (8)$$

Note that the likelihood $L(\mathbf{W})$ is the joint pdf $p_x(\mathbf{x}|\mathbf{W})$ for $\mathbf{x}$, but using MLE, it is treated as if it were a function of the parameter $\mathbf{W}$. If we substitute a commonly used leptokurtotic model joint pdf for the source signals $p_s(\mathbf{y}) = (1 - \tanh(\mathbf{y}^2))$, then

$$\ln L(\mathbf{W}) = \sum_i^M \sum_t^N \ln(1 - \tanh(\mathbf{w}_i^T \mathbf{x}^t)^2) + N \ln |\mathbf{W}|. \quad (9)$$

The matrix $\mathbf{W}$ that maximizes this function is the *maximum likelihood estimate* of the optimal unmixing matrix $\mathbf{W}^*$. Equation (9) provides a measure of similarity between the joint pdf of the extracted signals $\mathbf{y} = \mathbf{W} \mathbf{x}$ and the joint model pdf of the source signals $\mathbf{s}$. Having such a measure permits us to use standard optimization methods to iteratively update the unmixing matrix in order to maximize this measure of similarity.

ICA, Principal Component Analysis and Factor Analysis

ICA is related to conventional methods for analyzing large data sets such as **principal component analysis (PCA)** and **factor analysis (FA)**. Whereas ICA finds a set of source signals that are mutually independent, PCA and FA find a set of signals that are mutually decorrelated (consequently, neither PCA nor FA could extract speech signals, for example). The ‘forward’ assumption that signals from different physical processes are uncorrelated still holds, but the ‘reverse’ assumption that uncorrelated signals are from different physical processes does not. This is because lack of correlation is a weaker property than independence. In summary, independence implies a lack of correlation, but a lack of correlation does not imply independence.

6 Independent Component Analysis

Notes

1. We use the term signal and variable interchangeably here.
2. This is a seminal paper, which initiated the recent interest in ICA.
3. The matrix inverse is analogous to the more familiar inverse for scalar variables, such as $x^{-1} = 1/x$.
4. For brevity, we will abuse this technically correct, but lengthy, definition by stating that $p_s(s')$ is simply the probability that s adopts the value s' .
5. Up to an irrelevant permutation of rows.

Independent Pathway Model

The independent pathway model, as applied to genetically sensitive data, is a multivariate model in which the relationship between a group of variables is controlled by genetic and environmental common **latent factors** [3]. The common factors each have their own free paths to the observed variables and account for the between trait covariance. In addition, a set of specific genetic and environmental factors are specified accounting for variance that is not shared with the other variables in the model (residual or unique variance).

For twin data, two identical pathway models are modeled for each twin's set of variables with the genetic and environmental factors across twins (both common and specific) connected by the expected correlations. For the genetic factors, these correlations are unity for MZ twins and 0.5 for DZ twins.

For twins reared together, correlations for the shared (family) environmental effects are 1. Unshared environmental factors are uncorrelated cross twins (see Figure 1). For the specific factors to all have free loadings, the minimal number of variables in this model is three. For example, for two variables, the independent pathway model would have specific factors which are constrained to be equal, which is then equivalent to a **Cholesky decomposition**.

Similar to the *univariate genetic model*, the MZ and DZ ratio of the cross-twin within variable correlations (e.g., Twin 1 variable 1 and Twin 2 variable 1) will indicate the relative importance of genetic and environmental variance components for each variable. On the other hand, the MZ and DZ ratio of the cross-twin cross-trait correlations (e.g., Twin 1 variable 1 and Twin 2 variable 2) will determine the relative importance of genetic and environmental factors in the covariance between variables (i.e., genetic and environmental correlations). In addition, for any two variables it is possible to derive part of the phenotypic correlation determined by common genes

Figure 1 Independent Pathway Model for a Twin Pair: Ac, Cc, and Ec are the common additive, genetic, common shared, and common nonshared environmental factors, respectively. The factors at the bottom are estimating the variable specific A and E influences. For simplicity the specific C factors were omitted from the diagram

2 Independent Pathway Model

(which will be a function of both their h^2 (see **Heritability**) and genetic correlation) and by common shared and unique environmental effects (which will be a function of their c^2 and e^2 and the C and E correlation [see **ACE Model**]). For more information on genetic and environmental correlations between variables, see the general section on **multivariate genetic analysis**. Parameter estimates are estimated from the observed variances and covariances by **structural equation modeling**.

So what is the meaning and interpretation of this factor model? An obvious one is to examine the etiology of **comorbidity**. One of the first applications in this sense was by Kendler et al. [1], who illustrated that the tendency of self-report symptoms of anxiety and depression to form separate symptom clusters was mainly due to shared genetic influences. This means that genes act largely in a nonspecific way to influence the overall level of psychiatric symptoms. The effects of the environment were mainly specific. The conclusion was that separable anxiety and depression symptom clusters in the general population are largely the result of environmental factors.

Independent pathway models with more than one set of common genetic and environmental factors are also possible. Multivariate genetic analyses of

schizotypal personality data indicated that at least two latent factor (see **Latent Variable**) structures are required to account for the genetic covariation between the various components of schizotypy. The positive components (reality distortion, such as magical ideas, unusual perceptions, and referential ideas) and negative components (anhedonia, social isolation, and restricted affect) are relatively genetically independent, although each in turn may be related to cognitive disorganization [2].

Index Plots

An index plot is a **scatterplot** of data plotted serially against the observation (case) number within the sample. The data could consist of original observations or some derived measure, such as **residuals** or predicted values.

An index plot is a useful exploratory tool for two different situations and purposes. If the data are in serial order, for instance, because they were collected over time or systematically over a demographic area, the index plot can be an effective way of detecting patterns or trends; this version is sometimes known as a sequence plot. Furthermore, an index plot yields information about anomalous values (potential **outliers**) irrespective of whether the cases are in arbitrary or serial order.

As a simple illustration, consider the following 10 observations which are the times (in milliseconds) between reported reversals of orientation of a Necker cube obtained from a study on visual illusions: 302, 274, 334, 430, 489, 1697, 703, 978, 2745, 1656. Suppose that these represent 10 consecutive inter-reversal times for one person in a single experimental session. From Figure 1 we can see that times between reversals tend to increase the longer the person

Figure 1 Index plot of times (in msecs) between reported reversals of a Necker cube

viewed the cube, and also that cases 6 and 9 are unusually large and so are possibly outliers. Interestingly, observation 10, though almost the same time as observation 6, does not seem out of line with the general trend. On the other hand, if each of these 10 observations had represented an inter-reversal time for a different person, then we would certainly have reported all three cases as anomalous.

Industrial/Organizational Psychology

The field of industrial and organizational (IO) psychology has a long, rich statistical tradition. At the beginning of the twentieth century, experimental psychologists Walter Dill Scott and Hugo Münsterberg began applying psychological principles to the study of organizations, giving birth to the field of IO [2]. Around the same time, Frederick Taylor, an engineer, proposed principles of Scientific Management, which were designed to guide the selection, training, and reward of production workers [2]. From the time of Münsterberg, Scott, and Taylor, quantitative methodologies and statistical techniques have played a central role in the IO field of inquiry. This tradition continues as IO researchers apply sophisticated statistical procedures such as quantitative **meta-analysis**, **structural equation modeling**, and multilevel techniques (see **Linear Multilevel Models**). In addition, IO scholars contribute meaningfully to the improvement of existing techniques and the development of novel methodologies.

This entry, which is divided into four sections, provides a summary and description of statistical methods used in IO psychology. The first section lists the statistical techniques reported in two leading journals in the field. The second section summarizes the reasons that IO psychologists use several popular techniques. The third section illustrates contributions made by IO psychologists to the statistical analysis literature and the fourth notes the importance of statistics in IO theory development.

Statistical Methods Appearing in Two Leading IO Journals

Several reviews [1, 3, 4] of the research methods and statistical techniques used in IO and related fields appeared in the past decade or so. The purpose of this entry is to focus on statistical techniques rather than broader research design elements.

In a recent chapter, Austin et al. [1] reviewed the use of various research methods in IO for the 80-year period from 1920 to 2000 using articles from every tenth volume of *Journal of Applied Psychology* (*JAP*), which were coded for measurement, design,

and analytic issues. Our methodology was similar, but with three important differences. First, we used studies in two IO journals, *JAP* and *Personnel Psychology* (*PP*), in order to determine whether differences in statistical methods exist between publications. Second, we coded all studies in both journals for the nine-year period from 1995 to 2003 rather than sampling representative articles. Finally, we coded only statistical methods and not measurement or design issues. Our intention was to provide a thorough picture of the specific statistical methods currently used in the IO literature.

Results for *JAP* and *PP* are presented in Tables 1 and 2, respectively. These tables display the yearly percent and nine-year average for 10 techniques from 1995 to 2003. Because studies often used several statistical analyses, the percentages in each year sum to more than 100%. These data reveal that basic correlational statistics (see **Correlation Studies**), **multiple linear regression**, and **analysis of variance** (ANOVA)-based methods appear with the greatest frequency, while more sophisticated techniques such as meta-analysis, structural equation modeling, and hierarchical linear modeling (see **Hierarchical Models**) appear less often.

Two other notable features are prominent in Tables 1 and 2. First, there is consistency in the recent use of the techniques across time. Despite the fact that absolute percentage use varies across the time for particular methods (e.g., in *JAP* the percent use of multiple regression varied between 31 and 62%), the relative use appears quite stable over time. If techniques are treated as cases, the correlation between percentage use in *JAP* between 1995 and 1996 is quite large ($r = 0.96$). In fact, the average correlation of adjacent years was quite high (*JAP*, $\bar{r} = 0.97$, *PP*, $\bar{r} = 0.93$, Overall $\bar{r} = 0.95$).

Second, there has also been remarkable consistency between the journals. For example, if techniques are treated as cases, the correlation between percentage use in *JAP* and *PP* in 1995 was quite high ($r = 0.94$) with a similarly large average correlation ($\bar{r} = 0.94$) across journal within year. In short, the relative use of statistical techniques is similar across the two journals. One noticeable absolute difference, however, is exploratory factor analysis (see **Factor Analysis: Exploratory**). On average, 14% of studies that appeared in *JAP* reported exploratory factor analytic results compared with 24% of studies in *PP*. Given that this difference is not extremely

pronounced and that no other techniques show similar differences, we can conclude that technique use does not vary as a function of publication outlet in the two leading journals in the IO field.

Owing to the consistency of the observed results, data were collapsed across year and journal to produce an overall ranking of statistics use (see Table 3). Rankings are based on the percentage of all studies that report each statistical technique.

Table 3 makes clear the use of statistics in IO psychology. Correlations are the statistics most frequently used, appearing in approximately 78% of empirical research in *JAP* and *PP* during

the nine years. In a second tier, ANOVA-based statistics and multiple regression appeared in 49% and 43% of studies, respectively. Confirmatory factor analysis (see **Factor Analysis: Confirmatory**) (18%), exploratory factor analysis (17%), and **structural equation modeling** (11%) comprised a third tier. Meta-analysis (9%), chi-square analysis (see **Contingency Tables**) (8%), **logistic regression** (3%), and hierarchical linear modeling (2%) appeared in the fewest coded studies.

These techniques do not exhaust the statistical ‘toolbox’ used by IO psychologists. For example, statistical techniques such as **canonical correlation**

Table 3 ‘Top ten’ statistical techniques in IO psychology

Rank	Type of analysis	Overall percent
1	Correlation	78
2	Analysis of Variance	49
3	Multiple Regression	43
4	Confirmatory Factor Analysis	18
5	Exploratory Factor Analysis	17
6	Structural Equation Modeling	11
7	Meta-Analysis	9
8	Chi-square	8
9	Logistic Regression	3
10	Hierarchical Linear Modeling	2

and **discriminant function analysis** also appear in IO-related articles. Table 3 simply provides a ‘Top 10’ of the most widely used techniques.

Information not included in the tabled data, but especially striking, is the percentage of articles in which the primary focus was some aspect of statistics or research methodology. In *JAP*, 4.8% of the articles fell into this category, whereas 15.6% of the articles in *PP* addressed a primarily psychometric, methodological, or statistical issue. Although the nature of these articles varied widely, many reported results of statistical simulations, especially simulations of the consequences of certain statistical considerations (e.g., violations of assumptions). Others detailed the development or refinement of a given technique or analytic procedure.

Types of Analyses used in IO Research

Although the distinction between industrial and organizational psychology may be perceived as somewhat nebulous, treating the two areas as unique is a useful heuristic. Industrial psychologists traditionally study issues related to worker performance, productivity, motivation, and efficiency. To understand and predict these criterion variables, researchers explore how concepts such as individual differences (e.g., cognitive ability), workplace interventions (e.g., training programs), and methods of employee selection (e.g., job interviews) impact job-related outcomes. The statistical orientation of industrial psychology is largely a function of both the need to quantify abstract psychological constructs (e.g., cognitive ability, personality traits, job performance) and the practical difficulties faced in organizational settings (e.g., lack

of random assignment, measuring change due to a specific intervention).

Organizational psychologists generally study a broader range of topics including job attitudes, worker well-being, motivation, careers, and leadership. Addressing such issues presents a number of special statistical considerations. Measurement issues and practical considerations of data collection similarly confront organizational researchers. In addition, the hierarchical nature of organizations (i.e., individuals nested within groups nested within companies) presents unique methodological challenges for organizational psychologists. To address such factors, researchers often employ a variety of methodological and statistical techniques in order to draw strong conclusions.

Bivariate Correlation

As Table 3 illustrates, simple correlational analyses appear with the most frequency in IO research. For present purposes, correlational analyses include those that involve **Pearson correlations**, phi coefficients, biserial correlations, **point-biserial correlations**, and **terachoric correlations** methods that assess relationships between two variables. Simple correlations are reported in studies related to nearly every subarea (e.g., selection, training, job performance, work attitudes, organizational climate, and motivation).

One factor responsible for the ubiquity of correlations in IO research is the field’s interest in reliability information. Whether discussing predictor tests, criterion ratings, attitude scales, or various self-report measures, IO psychologists are typically concerned about the consistency of the observed data. Types of reliability reported include test-retest, alternate forms, internal consistency (most frequently operationalized through coefficient alpha), and interrater reliability.

Analysis of Variance

Statistics such as *t* Tests, analysis of variance, **analysis of covariance** (ANCOVA), **multivariate analysis of variance** (MANOVA), and multivariate analysis of covariance (MANCOVA) appear in studies that involve comparisons of known or manipulated groups. In addition, researchers often utilize *t* Tests and ANOVA prior to conducting other analyses to ensure that different groups do not differ significantly from one another on the

primary variables of interest. ANCOVA allows one to statistically control for confounding variables, or covariates, that potentially distort results and conclusions. Because organizational reality often precludes true experimentation, ANCOVA is quite popular among IO psychologists, especially those in organizations. MANOVA and MANCOVA are useful when dealing with either multiple criteria and/or repeated measurements (*see* **Repeated Measures Analysis of Variance**). For example, evaluating separate training outcomes or evaluating one or more outcomes repeatedly would warrant one of these techniques.

Multiple Regression

Multiple regression (MR) analysis is used in three situations: (1) identifying the combination of predictors that can most accurately forecast a criterion variable, (2) testing for mediated relationships (*see* **Mediation**), and (3) testing for the presence of statistical interactions (*see* **Interaction Effects**). The first situation occurs, for example, when IO psychologists attempt to identify the optimal set of predictor variables that an organization should utilize in selecting employees. Using MR in this manner yields potential practical and financial benefits to organizations by enabling them to eliminate useless or redundant selection tests while maintaining optimal prediction.

Utilizing MR for mediated relationships is increasingly common in IO and has led to both theoretical and practical advances. For example, researchers utilize MR when attempting to identify the intervening variables and processes that explain bivariate relationships between predictor variables (e.g., cognitive ability, personality traits) and relevant criteria (e.g., job performance). Moderated MR (*see* **Moderation**) is also encountered in IO, both to uncover complex relationships that main effects fail to capture and to identify important boundary conditions that limit the generalizability of conclusions. In addition, organizations use moderated MR to ensure that the empirical relationship between a given selection measure and the criterion is constant across subgroups and protected classes. Any evidence to the contrary, revealed by a significant interaction between predictor and group, necessitates that the organization abandon the procedure.

Confirmatory & Exploratory Factor Analysis

Exploratory factor analysis is used by IO psychologists to provide construct validity evidence in many substantive interest areas. In particular, exploratory factor analysis is used in situations that involve newly created or revised measures. Often, but not always, those using exploratory factor analysis for this purpose hope to find that all of the items load on a single factor, suggesting that the measure is unidimensional.

Confirmatory factor analysis has become increasingly popular in recent years, largely due to the increasing availability of computer packages such as LISREL and EQS (*see* **Structural Equation Modeling: Software**). Unlike exploratory techniques, confirmatory approaches allow one to specify an *a priori* factor structure, indicating which items are expected to load on which factors. Confirmatory factor analysis is also useful for investigating the presence of method variance, often through **multi-trait-multimethod** data, as well as ensuring that factor structures are similar, or invariant, across different subgroups.

Structural Equation Modeling

Because **path analysis** using ordinary least squares regression does not allow for the inclusion of measurement error, structural equation modeling is used to test hypothesized measurement and structural relationships between variables. Although the use of structural equation modeling in IO remains relatively infrequent (*see* Tables 1 and 2), this approach holds great promise, especially given the increasing sophistication of IO theories and models. As IO psychologists become more familiar with structural equation modeling and the associated software, its frequency should increase.

Meta-analysis

The use of meta-analytic techniques has led to several ‘truths’ in IO psychology. From the selection literature, meta-analytic results reveal that the best predictor of job performance across all jobs is cognitive ability and the best personality-related predictor is conscientiousness. More generally, meta-analysis led to the insight that disparities in results between studies are due largely to artifacts inherent in the measurement process. This conclusion has the potential

to change the ways that IO psychologists undertake applied and academic research questions. In addition to reducing the necessity of conducting local validation studies in organizations, academic researchers may choose meta-analytic methodologies rather than individual studies.

Logistic Regression

Logistic regression is useful for predicting dichotomous outcomes, especially when fundamental assumptions underlying linear regression are violated. This technique is especially common among IO psychologists examining issues related to employee turnover, workplace health and safety, and critical performance behaviors because the relevant criteria are dichotomous. For example, a researcher might use logistic regression to investigate the variables that are predictive of whether one is involved in a driving accident or whether a work team performs a critical behavior.

Contributions of IO Psychologists to the Statistics Literature

In addition to extensively utilizing existing analytical techniques, IO psychologists also conduct research in which they examine, refine, and create statistical tools. Largely driving these endeavors is the complex nature of organizational phenomena that IO psychologists address. Often, however, these statistical advances not only enable researchers and practitioners to answer their questions but also propagate new insights and questions. In addition, other areas both within and outside of the organizational realm often benefit by applying IO psychologists' statistical advances. In the following paragraphs, we list several statistical topics to which IO researchers made especially novel and significant contributions. This listing is not exhaustive with respect to topics or results but is presented for illustrative purposes.

IO researchers have made contributions in quantitative meta-analysis, especially in terms of validity generalization. Until the late 1970s, IO psychologists believed that to identify those variables that best predicted job performance, practitioners must conduct a validation study for each job within each organization. This notion, however, was radically altered by demonstrating that predictor-criterion validity often

'generalizes' across organizations, thereby suggesting that local validation studies are not always essential. Specifically, early meta-analytic work revealed that validity estimates from different organizations and situations often differed from each other primarily as a function of statistical artifacts inherent in the measurement process (e.g., sampling error, low reliability, range restriction) and not as a result of specific contextual factors. These insights led to several lines of statistical research on how best to conceptualize and correct for these artifacts, especially when the primary studies do not contain the necessary information (e.g., reliability estimates).

Beginning in the early 1980s, IO psychologists also made strides in examining and developing various aspects of structural equation modeling. Some of these advances were related to the operationalization of continuous moderators, procedures for evaluating the influence of method variance, techniques for assessing model invariance across groups, the use of formative versus reflective manifest variables, and the impact of item parceling on model fit. Notably, some developments engendered novel research questions that, prior to these advances, IO psychologists may not have considered. For example, recent developments in latent growth modeling allowed IO psychologists to study how individuals' changes over time on a given construct impact or are impacted by their standing on another variable. Thus, to study how changes in workers' job satisfaction influence their subsequent job performance, the researcher can now measure how intra individual *changes* in satisfaction affect performance, instead of relying on a design in which Time 1 satisfaction simply is correlated with Time 2 performance.

Yet another statistical area that IO psychologists contributed to is difference scores. Organizational researchers traditionally utilized difference scores to examine issues such as the degree of 'fit' between a person and a job or a person and an organization. Throughout the 1990s, however, a series of articles highlighted several problematic aspects of difference scores and advanced the use of an alternative technique, polynomial regression, to study questions of fit and congruence.

The preceding discussion covers only a few of IO psychology's contributions to statistical methods. Given the continuing advances in computer technology as well as the ever-increasing complexity of management and organizational theory, IO psychologists

probably will continue their research work on statistical issues in the future.

The Role of Statistics in Theory Development

This entry illustrates the interest that IO psychologists have in quantitative methods. Although IO psychologists pride themselves on the relative methodological rigor and statistical sophistication of the field, our focus on these issues is not without criticism. For example, IO psychologists may be viewed as overly concerned with psychometric and statistical issues at the expense of underlying constructs and theory. To be sure, this criticism may once have possessed some merit. Recently, however, IO psychologists have made significant theoretical advancements as evidenced by recent efforts to understand, instead of simply predict, job performance and other important criteria. Without our embrace of sophisticated statistical analyses, this theoretical focus might not have emerged. Procedures such as structural equation modeling, hierarchical linear modeling, and meta-analysis have enabled researchers to assess complex theoretical formulations, and have allowed practitioners to better serve organizations and workers. Moreover, many other areas of psychology often benefit from the statistical skills of IO psychologists, especially

in terms of the availability of new or refined techniques. Thus, IO psychologists continue embracing statistics both as an instrumental tool to address theoretical research questions and as an area of study and application worthy of addressing in its own right.

Influential Observations

Introduction

An influential observation is one that has a large effect on our inferences. To measure the influence of an observation, we often compare the inferences we would make with all the data to those made excluding one observation at a time.

One of the earliest influence diagnostics, which is still widely used, is due to Cook [4]. In the context of a linear model $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$, where $\mathbf{X}$ is the $n \times p$ design matrix, he defined the influence of the i th observation on the estimate of $\boldsymbol{\beta}$ as

$$D_i = \frac{(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)})^T \mathbf{X}^T \mathbf{X} (\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)})}{ps^2}, \quad (1)$$

where $\hat{\boldsymbol{\beta}}$ is the usual least squares estimate of $\boldsymbol{\beta}$, $\hat{\boldsymbol{\beta}}_{(i)}$ is the least squares estimate omitting the i th observation and s^2 is the residual mean square. This can also be written as

$$D_i = \frac{t_i^2}{p} \frac{v_i}{(1 - v_i)}, \quad (2)$$

where

$$t_i = \frac{(y_i - \mathbf{x}_i^T \hat{\boldsymbol{\beta}})}{s}$$

is the standardized residual and $v_i = \mathbf{x}_i(\mathbf{X}^T \mathbf{X})^{-1} \mathbf{x}_i^T$ is the leverage, a measure of how unusual the regressor values are. Thus, an influential observation can be a gross outlier (large $|t_i|$), have a very unusual set of regressor values (large v_i), or a combination of the two.

Consider Figure 1, an example of a simple linear regression (see **Multiple Linear Regression**). The observations labelled * on their own satisfy a simple linear regression model. Observation A is an outlier but has low leverage and is not very influential because $\hat{\boldsymbol{\beta}}$ will not be affected much by it. Observation B has a high leverage but has a small residual and is not influential. Observation C is influential, has high leverage, and a large residual.

At about the time that Cook's paper was published, a number of other case deletion diagnostics were proposed, which are similarly functions of t_i and v_i .

Figure 1 A simple linear regression with added outliers and influential observations

Writing $F_i = \frac{t_i^2(n - p - 1)}{n - p - t_i^2}$, we have

$$\begin{aligned} & \left(\frac{n - p}{p} F_i \right) \left(\frac{v_i}{1 - v_i} \right), \quad [17] \\ & \left(1 - \frac{t_i^2}{n - p} \right) (1 - v_i), \quad [1] \\ & \left(\frac{t_i^2}{p} \right) v_i, \quad \left(\frac{F_i}{p} \right) v_i, \quad [5] \end{aligned} \quad (3)$$

Others, for example Atkinson [2], proposed similar measures but using $s_{(i)}^2$. In general, the same observations are detected as influential by these different measures and many analysts would look at t_i , v_i as well as their preferred influence diagnostic.

Theoretical work on influence has often been based on the influence curve [9].

Suppose $X_1, X_2, \dots, X_n$ are a random sample of observations on X and a statistic of interest, T , can be written as a functional $T(F_n)$ of the empirical distribution function $\hat{F}$ of $X_1, X_2, \dots, X_n$. If X has cdf F , then the influence curve of T evaluated at $X = x$ is

$$IC_{T,F}(x) = \lim_{\varepsilon \rightarrow 0_+} \frac{T[(1 - \varepsilon)F + \varepsilon\delta_x] - T(F)}{\varepsilon} \quad (4)$$

2 Influential Observations

It gives a measure of the influence on T of adding an observation at x as $n \rightarrow \infty$.

Several finite sample versions of the influence curve have been suggested. The empirical influence curve (EIC) is obtained by substituting the sample cdf $\hat{F}$ for F in the influence curve. For linear models,

$$\begin{aligned} EIC(\mathbf{x}, y) &= n(\mathbf{X}^T \mathbf{X})^{-1} \mathbf{x} (y - \mathbf{x}^T \hat{\boldsymbol{\beta}}) \\ EIC_i &= EIC(\mathbf{x}_i, y_i) = n(\mathbf{X}^T \mathbf{X})^{-1} \mathbf{x}_i e_i, \end{aligned} \quad (5)$$

where e_i is the crude residual.

The sample influence curve (SIC) is obtained by taking $F = \hat{F}$ and $\varepsilon = -1/(n-1)$ in the definition of the influence curve. This leads to

$$SIC_i = -(n-1)(T(\hat{F}_{(i)}) - T(\hat{F})), \quad (6)$$

which in the case of the linear model gives

$$\begin{aligned} SIC_i &= (n-1)(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)}) \\ &= \frac{(n-1)(\mathbf{X}^T \mathbf{X})^{-1} \mathbf{x}_i e_i}{1 - v_i}. \end{aligned}$$

See [6] for more details and relationships between these measures.

A complicating factor in considering influence is that, in general, it is not ‘additive’. A pair of observations may not be individually influential but if both are deleted they may be jointly influential. With large data sets it is not clear what size sets of observations should be considered and computation may be a problem.

Bayesian case deletion diagnostics, looking at the effect on the posterior or predictive distribution, were considered by for example, Johnson and Geisser [10] and Pettit and Smith [15]. They used symmetric Kullback Leibler distance, for example,

$$I(i) = \int \log \frac{p(\boldsymbol{\theta}|\mathbf{y})}{p(\boldsymbol{\theta}|\mathbf{y}_{(i)})} [p(\boldsymbol{\theta}|\mathbf{y}) - p(\boldsymbol{\theta}|\mathbf{y}_{(i)})] d\boldsymbol{\theta}, \quad (7)$$

where $\boldsymbol{\theta}$ represents the parameters of interest. For vague prior information, the Bayesian diagnostic due to Pettit and Smith can be written as

$$I(i) = \frac{1}{2} \frac{v_i}{1 - v_i} (v_i + (2 - v_i)t_i^2). \quad (8)$$

Note that unlike most of the frequentist diagnostics it is not zero if t_i is. This is because $I(i)$ measures the effect on the whole posterior. Deleting an observation with $t_i = 0$ would not affect $\hat{\boldsymbol{\beta}}$ but may affect its variance if v_i is large.

The idea of using case deletion or a sample influence curve to measure influence has been extended to many situations, for example,

- **Principal component analysis** [7, 14]
- **Time series** [3]
- **Measures of skewness** [8]
- **Correspondence analysis** [13]
- **Cluster analysis** [11]

These may show rather different characteristics to the linear model case. For example, in principal component analysis, Pack et al. [14] show that influence is approximately additive. They also show that one influential observation, in their case caused by two measurements being swapped, can have a surprisingly large effect with the second principal component being due to this one observation.

Although influence of observations on a parameter estimate is of importance, another class of problems, model choice, has received less attention. Pettit and Young [16] and Young [18] discussed the influence of one or more observations on a Bayes factor. They defined the effect of observation d on a Bayes factor comparing models M_0 and M_1 as the difference in log Bayes factors based on all the data and omitting observation d ,

$$k_d = \log_{10} \left(\frac{p(\mathbf{y}|M_0)}{p(\mathbf{y}|M_1)} \right) - \log_{10} \left(\frac{p(\mathbf{y}_{(d)}|M_0)}{p(\mathbf{y}_{(d)}|M_1)} \right). \quad (9)$$

The diagnostic k_d can also be written as the difference in log conditional predictive ordinates (CPO) under the two models. CPO is an outlier measure. In general, an observation will have a large influence if it is an outlier under one model but not the other.

For example, when testing a mean, consider a normal sample with one observation contaminated by adding δ . Typical behavior of $|k_d|$ is to slowly increase to a maximum as δ increases and then to fall. For small δ , the contaminant is an outlier under M_0 but not M_1 . As δ increases, it becomes an outlier under both models and loses its influence.

Jolliffe and Lukudu [12] find similar behavior when looking at the effect of a contaminant on the T statistic.

The question remains as to what an analyst should do when they find an observation is influential. It should certainly be reported. Sometimes, as in the Pack et al. [14] example, it is a sign of a recording error that can be corrected. If a designed experiment results in an influential observation, it suggests that taking some more observations in that part of the design space would be a good idea. Another possibility is to use a more robust procedure that automatically down weights such observations. It may also suggest that a hypothesized model does not hold for the whole of the space of regressors.

Information Matrix

Fisher information is a key concept in the theory of statistical inference [4, 7] and essentially describes the amount of information data provide about an unknown parameter. It has applications in finding the variance of an estimator, in the asymptotic behavior of **maximum likelihood estimates**, and in Bayesian inference (*see Bayesian Statistics*). To define Fisher information, let $\mathbf{X} = (X_1, \dots, X_n)$ be a random sample, and let $f(\mathbf{X}|\boldsymbol{\theta})$ denote the probability density function for some model of the data, which has parameter vector $\boldsymbol{\theta} = (\theta_1, \dots, \theta_k)$. Then the Fisher information matrix $I_n(\boldsymbol{\theta})$ of sample size n is given by the $k \times k$ symmetric matrix whose ij th element is given by the covariance between first partial derivatives of the log-likelihood,

$$I_n(\boldsymbol{\theta})_{i,j} = \text{Cov} \left[\frac{\partial \ln f(\mathbf{X}|\boldsymbol{\theta})}{\partial \theta_i}, \frac{\partial \ln f(\mathbf{X}|\boldsymbol{\theta})}{\partial \theta_j} \right]. \quad (1)$$

An alternative, but equivalent, definition for the Fisher information matrix is based on the expected values of the second partial derivatives, and is given by

$$I_n(\boldsymbol{\theta})_{i,j} = -E \left[\frac{\partial^2 \ln f(\mathbf{X}|\boldsymbol{\theta})}{\partial \theta_i \partial \theta_j} \right]. \quad (2)$$

Strictly, this definition corresponds to the *expected* Fisher information. If no expectation is taken, we obtain a data-dependent quantity that is called the *observed* Fisher information. As a simple example, consider a normal distribution with mean μ and variance σ^2 , where $\boldsymbol{\theta} = (\mu, \sigma^2)$. The Fisher information matrix for this situation is given by $I_n(\boldsymbol{\theta}) = \begin{pmatrix} n/\sigma^2 & 0 \\ 0 & n/2\sigma^4 \end{pmatrix}$.

It is worth noting two useful properties of the Fisher information matrix. Firstly, $I_n(\boldsymbol{\theta}) = nI_1(\boldsymbol{\theta})$, meaning that the expected Fisher information for a sample of n independent observations is equivalent to n times the Fisher information for a single observation. Secondly, it is dependent on the choice of parameterization, that is, how the parameters of a model are combined in the model's equation to define the probability density function. If the parameters are changed into new parameters by describing the latter as a function of the former, then the information matrix of the revised parameters can be found

analytically from the information matrix of the old parameters and the function that transforms the old parameters to the new ones [6].

The Cramer–Rao Inequality

Perhaps the most important application of the Fisher information matrix in statistics is in determining an absolute lower bound for the variance of an arbitrary unbiased estimator. Let $T(\mathbf{X})$ be any statistic and let $\psi(\boldsymbol{\theta})$ be its expectation such that $\psi(\boldsymbol{\theta}) = E[T(\mathbf{X})]$. Under some regularity conditions, it follows that for all $\boldsymbol{\theta}$,

$$\text{Var}(T(\mathbf{X})) \geq \frac{\left(\frac{d\psi(\boldsymbol{\theta})}{d\boldsymbol{\theta}} \right)^2}{I_n(\boldsymbol{\theta})}. \quad (3)$$

This is called the *Cramer–Rao inequality* or the *information inequality*, and the value of the right-hand side of (3) is known as the famous *Cramer–Rao lower bound* [5]. In particular, if $T(\mathbf{X})$ is an unbiased estimator for $\boldsymbol{\theta}$, then the numerator becomes 1, and the lower bound is simply $1/I_n(\boldsymbol{\theta})$. Note that this explains why $I_n(\boldsymbol{\theta})$ is called the ‘information’ matrix: The larger the value of $I_n(\boldsymbol{\theta})$ is, the smaller the variance becomes, and therefore, we would be more certain about the location of the unknown parameter value. It is straightforward to generalize the Cramer–Rao inequality to the multiparameter case [6].

Asymptotic Theory

The maximum likelihood estimator has many useful properties, including reparametrization-invariance, consistency, and sufficiency. Another remarkable property of the estimator is that it achieves the Cramer–Rao minimum variance asymptotically; that is, it follows under some regularity conditions that the sampling distribution of a maximum likelihood estimator $\hat{\boldsymbol{\theta}}_{ML}$ is asymptotically unbiased and also asymptotically normal with its variance–covariance matrix obtained from the inverse Fisher information matrix of sample size 1, that is, $\hat{\boldsymbol{\theta}}_{ML} \rightarrow N(\boldsymbol{\theta}, I_1(\boldsymbol{\theta})^{-1}/n)$ as n goes to infinity.

Bayesian Statistics

Fisher information also arises in Bayesian inference (*see Bayesian Statistics*). The information matrix

2 Information Matrix

is used to define a noninformative prior that generalizes the notion of ‘uniform’. This is called *Jeffreys’ prior* [3] defined as $\pi_J(\boldsymbol{\theta}) \propto \sqrt{|I_1(\boldsymbol{\theta})|}$ where $|I_1(\boldsymbol{\theta})|$ is the determinant of the information matrix. This prior can be useful for three reasons. First, it is reparametrization-invariant so the same prior is obtained under all reparameterizations. Second, Jeffreys’ prior is a *uniform* density on the space of probability distributions in the sense that it assigns equal mass to each ‘different’ distribution [1]. In comparison, the uniform prior defined as $\pi_U(\boldsymbol{\theta}) = c$ for some constant c assigns equal mass to each different value of the parameter and is not reparametrization-invariant. Third, Jeffrey’s prior is the one that maximizes the amount of information about $\boldsymbol{\theta}$, in the Kullback–Leibler sense, that the data are expected to provide [2].

Information Theory

The first approach to formulating information theory was the communication model by **Shannon** and Weaver. Both authors worked at the Bell Laboratories. The aim of this research was the development of theoretical tools for the optimization of telephone engineering. The goal was the identification of the quickest and most efficient way to get a message from one location to another. The crucial questions were: (a) How can communication messages be converted into electronic signals most efficiently, and (b) how can signals be transmitted with a minimum of error? The results of this research culminated in the classic ‘The mathematical theory of communication’ [4].

The term *communication* can be used in a very broad sense. It includes all cases in which ideas can influence each other. Examples of such cases include words, writings, music, paintings, theater, opera, or, in brief, any human behavior. Because of the breadth of the definition, various problems of communication need to be considered. Shannon and Weaver [4] propose a three-level classification of communication problems:

1. Level A: technical problems;
2. Level B: semantic problems; and
3. Level C: effectiveness problems.

Level A is the one that is most accessible to analysis and engineering. *Technical problems* concern the accuracy of transmissions from sender (source) to receiver. Such a transmission can be an order of signs (written language), signals that change continuously (phone conversations, wireless connections), or two-dimensional patterns that change continuously (television). *Semantic problems* concern the interpretation of a message that the source sent to the receiver. Finally, *effectiveness problems* concern the success of the transmission: does a message lead to the intended response at the receiver’s end?

Levels B and C use the degree of accuracy determined by Level A. This implies that any restriction made on Level A has effects on Levels B and C. Thus, a mathematical description of technical problems is also of use at Levels B and C. These levels cover the philosophical issues of information theory. In the next section, we discuss some of the mathematical and technical issues of Level A.

Mathematical and Technical Issues of Information Theory

Shannon and Weaver [4] defined *information* as a measure of one’s freedom of choice when selecting a message. In this sense, *information* is equivalent to meaning. In different words, information refers to what could have been said instead of what has been said. As a system, communication can be represented as in Figure 1.

This communication model includes an information source and a receiver. Typically, the source encodes a message by translating it using a code in the form of bits. The word *bit* was proposed for the first time by **John W. Tukey**. It stands for *binary digit*, 0 and 1. To understand a message, the receiver must be able to decode the message. Thus, a code is a language or another set of symbols that can be used to transmit an idea through one or more channels.

An additional element in the communication model in Figure 1 is the *noise*. During a transmission, it can occur that undesirable bits of code are added to a message. Such disturbances, unintended by the source of the original information are, for instance, atmospheric disturbances, distortions of image and sound, or transmission errors.

Another reason for distortion of transmissions is channel overload. More information is fed into a channel than the channel can possibly transmit (see channel capacity, below). Because of the overload, information will be lost, and the received information will be different than the sent information.

A key question concerns the measurement of the amount of information in a message. There are two types of messages, coded as 0 and 1. The amount of information is defined as the logarithm of the number of possible choices. By convention, the logarithm with base 2 is used. If a message contains only one element of information, the amount of information transmitted is the logarithm of 2, base 2, that is, 1. This number is also called *one bit*. When a message contains four elements, there are 2^4 alternatives, and the amount of information contained in this message is $\log_2 16 = 4$.

To illustrate, consider a message with three elements. This message can contain the following eight strings of zeros and ones: 000, 001, 010, 011, 100, 101, 110, and 111. The amount of information carried by this message is $\log_2 8 = 3$, or 3 bits. In general, the amount of information contained in a message

Figure 1 The communication system

with N elements is

$$H = \log_2 N, \quad (1)$$

which is known as the *Hartley formula* [2].

These first examples illustrate the theoretical constructs. An example of a practical application of the concept of information is the following: consider a person speaking. Let the elementary unit of this activity be the individual word. Thus, the speaker can select words and produce a sentence using these words. Let this sentence be the message. From an information theory perspective, it seems clear that after a particular word, it is more or less likely that another particular word will follow. For example, the probability that a noun follows after the word ‘the’ is higher than the probability that an adverb follows.

Some Background

The mathematical background of the study of sequences of words or other messages is given by Stochastic Processes and by **Markov Chains**. If a speaker builds a message word by word, the probability of the next word is considered given only by the immediately preceding word, but not by the words used before. This is the concept of a first-order Markov Chain. The mathematical and statistical terminology used in this context is that of an *Ergodic Markov Chain*, the most important case of Markov chains. In more technical terms, let P_i be the probability of state i , and $p_i(j)$ the probability of arriving at state j coming from state i . This probability is also called the *transition probability*. For a stationary process, the following constraint holds:

$$P_j = \sum_i P_i p_i(j). \quad (2)$$

In the ergodic case, it can be shown that the probability $P_j(N)$, that is, the probability of reaching state j after N signs converges to the equilibrium values

for $N \rightarrow \infty$. This statement holds for any starting distribution.

The term that takes all of the above concepts into account is *entropy*. Entropy is a function of the occurring probabilities of reaching a state in a transmission generating process, and the probability of transition from one state to another. Entropy displays the logarithm of these probabilities. Thus, the entropy can be viewed as a generalization of the logarithmic measure defined above for the simple cases. In other words, the entropy H is equivalent to information, and is, according to the Hartley formula, defined as

$$H = - \sum_{i=1}^N p_i \log p_i, \quad (3)$$

where $p_1, \dots, p_n$ are the probabilities of particular messages from a set of N independent messages.

The opposite of *information* is *redundancy*. Redundant messages add nothing or only little information to a message. This concept is important because it helps track down and minimize noise, for example, in the form of repeating a message, in a communicating system.

The aim of the original theory of information [3] was to find out how many calls can be transmitted in one phone transmission. This number is called the *channel capacity*. To determine channel capacity, it is essential to take the length of signs into account. In general, the channel capacity C is

$$C = \lim_{T \rightarrow \infty} \frac{\log N(T)}{T}, \quad (4)$$

where $N(T)$ is the number of permitted signals of length T . Based on these considerations, the following fundamental theorem of Shannon and Weaver can be derived: Using an appropriate coding scheme, a source is able to transmit messages via the transmission channel at an average transmission rate of almost C/H , where C is the channel capacity in bits per second and H is the entropy, measured in bits per sign. The exact value of C/H is never reached, regardless of which coding scheme is used.

Applications

Applications of information theory can be found, for instance, in electronics and in the social sciences. In electronics, information theory refers to engineering principles of transmission and perception. When, for instance, a person speaks into a telephone, the phone translates the sound waves into electrical impulses. The electrical impulses are then turned back into sound waves by the phone at the receiving end. In the social sciences, it is of interest how people are able or unable to communicate based on their different experiences and attitudes. An example of the use of information theory is given by Aylett [1].

The author presents a statistical model of the variation of clarity of speech. *Clarity* refers to the articulation of a word in various situations; for instance, spontaneous speech or reading words. He then investigated the degree to which a model formed for carefully articulated speech accounts for data from natural speech. Aylett states that the clarity of individual syllables is a direct consequence of a transmission process, and that a statistical model of clarity change provides insight into how such a process works. Results suggest that, if the speaker is in a noisy environment, the information content of the message should be increased in order to maximize the probability that the message is received.

Statistically, Aylett described the model of clarity variation using a density function that is composed of a mixture of Gaussians (see **Finite Mixture Distributions**)

$$Clarity = \frac{1}{n} \sum_{i=1}^n \log(p(x_i|M)), \quad (5)$$

where M is a clear speech model and n is a set of acoustic observations. The method for modeling clear speech and for comparing this model to actual speech is described in more detail in [1].

The first step of Aylett's data analysis concerned the relationship between the model and the psycholinguistic measures. Results indicate only a weak relationship between loss of intelligibility and clarity.

However, there was a stronger relationship between the speaker's average intelligibility in running speech and the average clarity of the speaker's running speech. In addition, the less intelligible a speaker's speech is, the poorer the fit of the final statistical model becomes.

In a second analytic step, the relationships between redundancy, articulation, and recognition were examined. Results suggest that clear speech is easier to recognize and to understand. Syllables that are pronounced with an emphasis are clearer than syllables with no emphasis. Aylett's model supports the assumption that out-of-context, high redundancy items in poorly articulated language are difficult to recognize. In addition, the model explains why speakers control levels of redundancy to improve the transmission process.

Aylett's study is an example of applying basic principles of information theory to modern psychological concepts. It is obvious that the main concepts defined by Shannon and Weaver [4] are not restricted to be used for modeling telephone transmission, but can be employed to answer a number of questions in the social and behavioral sciences, and statistics [5].

Instrumental Variable

The errors-in-variables model differs from the classical linear regression model in that the 'true' explanatory variables are not observed directly, but are masked by measurement error. For such models,

additional information is required to obtain consistent estimators of the parameters. A variable that is correlated with the true explanatory variable but uncorrelated with the measurement errors is one type of additional information. Variables meeting these two requirements are called *instrumental variables*.

Intention-to-Treat

A key type of intervention study is the so-called randomized **clinical trial** (RCT) [2–4, 9, 10]. In its basic form, a sample of volunteers is randomly split over two or more treatment groups. In doing so, baseline and other patient characteristics are ensured to be, on average, equal across groups, and, hence, differences in response on a clinical outcome can be ascribed solely and entirely to differences in treatment allocation. This is a powerful paradigm, since observed differences or, equivalently, associations between treatment assignment and differences in relevant outcome variables can then be given a causal interpretation. Apart from simple **randomization**, a number of variations to the randomization theme are in common use, such as **blocked randomization** and stratified randomization (*see Stratification*), to reduce the impact of chance, and, hence, to increase precision. But, whichever form is chosen, the goal is the same: to retain the interpretation of the average difference in response between the treatment groups as stemming from the treatment allocation itself, and not coming from other nuisance or confounding characteristics. The ability to reach an unbiased conclusion is a powerful asset of such a study, not shared by, for example, epidemiological or other observational studies.

However, in practice, this paradigm is jeopardized in two important ways, both of which stem from the fact that clinical trials are conducted in human subjects having a free will and, rightly so, carefully protected rights. First, some patients may not receive the treatment as planned in the study protocol, because they are sloppy with, for example, a rigorous treatment schedule, and, hence, may take less medication. Some may take more than planned at their own initiative. In rare cases, patients may even gain access to medication allocated to the other treatment arm(s). Hence, while patients remain on study, they do not follow the treatment regimen. Note that this is in line with actual practice, also outside of the clinical trial setting. Second, some patients may leave the study, some rather early after their enrollment in the trial, some at a later stage. In such cases, virtually no data or, at best, only partial data are available. This is bound to happen in studies that run over a relatively long period of time and/or when the treatment protocol is highly demanding. Again, this is in line

with the patient's rights. Having witnessed the terrible experiments conducted on humans during World War II, the Convention of Helsinki was passed. Ever since, clinical trial participation requires the patient to be given a clear and understandable statement about risks and benefits. This should be done by a qualified medical professional, and in the presence of an impartial witness. All have to sign the informed consent form. Then, still, the patient retains the right to withdraw from the study at any point in time, without the need to defend his or her decision.

Thus, after data have been collected, the researcher is faced with an incomplete sample, consisting of patients some having incomplete follow-up information, and some having followed a deviating treatment regimen.

It would then be tempting to adjust statistical analysis for discrepancies between the actual data and the way the study had been planned (*see Missing Data*). Such an approach is termed *as treated*. However, there is a key problem with such an analysis. Since dropout rates and/or deviations between the planned and the actual treatment regimen may be different between different treatment arms, the justification arising from randomization is undermined. Put differently, analyzing the data 'as treated' is likely to introduce confounding and, hence, bias.

As an answer to this, the so-called 'intention-to-treat' (ITT) principle has been introduced. It refers to an analysis that includes all randomized patients in the group to which they were randomly assigned, regardless of their adherence to the entry criteria, regardless of the treatment they actually received, and regardless of subsequent withdrawal from treatment or deviation from the protocol. While this may look strange and even offending to the novice in the clinical trial field, the principle is statistically widely accepted as providing valid tests about the null hypothesis of no treatment effect. It also refers to actual practice, where it is even more difficult to ensure patients follow the treatment as planned. The term 'intention to treat' appears to have been coined by Hill [5]. An early but clear account can be found in [11]. Careful recent accounts are given by Armitage [1] and McMahon [7].

If one is interested in the true efficacy of a medicinal product or an intervention beyond simply testing the null hypothesis, an ITT analysis is not the right tool. However, because of the bias referred to earlier, an analysis 'as treated' is not appropriate

either since it is vulnerable to bias. A large part of the recent incomplete data and so-called noncompliance literature is devoted to ways of dealing with this question [12]. This issue is nontrivial since the only definitive way to settle it would be to dispose of the unavailable data, which, by definition, is impossible. Whatever assumptions made to progress with the analysis, they will always be unverifiable, at least in part, which typically results in sensitivity to model assumptions.

The translation of the ITT principle to longitudinal clinical studies (see **Longitudinal Data Analysis**), that is, studies where patient data are collected at multiple measurement occasions throughout the study period, is a controversy in its own right. For a long time, the view has prevailed that only carrying the last measurement (also termed *last value*) actually obtained on a given patient forward throughout the remainder of the follow-up period is a sensible approach in this respect. (This is known as last observation carried forward (LOCF).) With the advent of modern likelihood-based longitudinal data analysis tools, flexible modeling approaches that avoid the need for both imputation and deletion of data have come within reach. Part of this discussion can be found in [6, 8].

Interaction Effects

In statistical analysis, we often examine the simultaneous effect of two or more variables on some outcome. Interaction effects refer to the effects of particular unique combinations of variables on an outcome that would not be expected from their average effects. Consider a statistics professor who is trying to increase performance in her graduate statistics course. She uses two study aids: a detailed study guide and a comprehensive review session. In an experiment, she tries all four combinations of providing or not providing the study guide with providing or not providing the review session. Suppose the result is as shown in Figure 1(a). When there is a study guide (left-hand pair of bars), the review session adds 30 points to performance; the same is true when there is no study guide (right-hand pair of bars). Looked at the other way, with no review session (black bars), the study guide adds 20 points to performance; with a review session (striped bars), the study guide adds the same 20 points. There is no interaction between the study guide and the review session; each has a constant effect on test performance regardless of the other.

Now, consider an alternative outcome given in Figure 1(b). When there is no study guide (right-hand pair of bars), the review session adds 30 points to performance, just as before. But, when there is a study guide (left-hand pair of bars), the review session lowers scores 10 points, perhaps due to information overload! Looked at the other way, with no review session (black bars), the study guide adds 50 points (from 40 to 90). Yet, with the review session (striped bars), the study guide adds only 10 points (from 70 to 80). The effect of each study aid depends on the other study aid; there is an interaction between the study guide and the review session.

Three Characterizations of Interactions

There are three interrelated characterizations of interactions, as (a) conditional effects, (b) nonadditive effects (*see Additive Models*), and (c) as residual effects over and above the individual effects of each variable. These are best explained with reference to the table of arithmetic means associated with Figure 1, given in Table 1. In the table, a cell mean

Figure 1 Effects of a study guide and a review session on statistics examination performance. In Figure 1(a), there is no interaction. In Figure 1(b), study guide and review session interact

refers to the mean at one combination of study guide (yes/no) and review session (yes/no), for example, the cell mean of 70 in Table 1(a) for the cell, 'No Study Guide/Review Session'. The column means are average effects of the study guide variable collapsed over review session; the row means are average effects of

2 Interaction Effects

Table 1 Cell means, marginal means (row and column means), and grand mean for performance on a statistics examination as a function of study guide and review session

	Table 1(a): No interaction			Table 1(b): Interaction		
	Study guide		Row mean	Study guide		Row mean
	Yes	No		Yes	No	
Review Session						
Yes	90	70	80	80	70	75
No	60	40	50	90	40	65
Column Mean	75	55	65	85	55	70

review session collapsed over study guide. The grand mean (65 in Table 1(a)) is average performance over all four cells.

Interactions as Conditional Effects

Conditional effects are the effects of one variable at a particular level of another variable. The effect of the review session when a study guide is also given is one conditional effect; effect of review session without a study guide is a second conditional effect. When there is no interaction, as in Table 1(a), the conditional effects of a variable are constant over all levels of the other variable (here the constant 30-point gain from the review session). If there is an interaction, the conditional effects of one variable differ across values of the other variable. As we have already seen in Table 1(b), the effect of the review session changes dramatically, depending on whether a study guide has been given: a 30-point gain when there is no study guide versus a 10-point loss in the presence of a study guide. One variable is said to be a **moderator** of the effect of the other variable or *to moderate* the effect of the other variable; here we say that study guide moderates the effect of review session.

Interactions as Nonadditive Effects

Nonadditive effects signify that the combination of two or more variables does not produce an outcome that is the sum of their individual effects. First, consider Table 1(a), associated with Figure 1(a) (no interaction); here, the cell means are *additive effects* of the two variables. In Table 1(a), the row means tell us that the average effect of study guide is a 30-point gain, from 50 to 80; the column means tell us that the average effect of review session is 20 points, from 55 to 75. With neither study guide nor review

session, the cell mean is 40; introducing the study guide yields a 30-point gain to a cell mean of 70; then, introducing the review session yields another 20-point gain to a cell mean of 90. Table 1(b), associated with Figure 1(b) (interaction) contains *nonadditive effects*. The row mean shows a 10 point average gain from the study guide, from 65 to 75. The column mean shows as a 30-point gain from the review session, from 55 to 85. However, the cell means do not follow the pattern of the marginal means. With neither study guide nor review session, the cell mean is 40. Introducing the study guide yields a 50-point gain to 90, and not the 30-point gain expected from the marginal mean; then, introducing the review session on top of the study guide yields a loss of 10 points, rather than the gain of 10 points expected from the marginal means. The unique combinations of effects represented by the cells do not follow the marginal means.

Interactions as Cell Residuals

The characterization of interactions as cell **residuals** [8] follows from **the analysis of variance** framework [5, 6]. By *cell residual* is meant the discrepancy between the cell mean and the grand mean that would not be expected from the additive effects of each variable. When there is an interaction between variables, the cell residuals are nonzero and are pure measures of the amount of interaction. When there is no interaction between variables, the cell residuals are all zero.

Types of Interactions by Variable (Categorical and Continuous)

Categorical by Categorical Interactions

Thus far, our discussion of interactions is in terms of variables that take on discrete values, categorical

by categorical interactions, as in the factors in the analysis of variance (ANOVA) framework. In the ANOVA framework, the conditional effects of one variable at a value of another variable, for example, the effect of review session when there is no study guide, is referred to as a *simple main effect*. See [5] and [6] for complete treatments of interactions in the ANOVA framework.

Categorical by Continuous Variable Interactions

We can also characterize interactions between categorical and continuous variables. To continue our example, suppose we measure the mathematics ability of each student on a continuous scale. We can examine whether mathematics ability interacts with having a review session in producing performance on a statistics examination. Figure 2(a) illustrates an interaction between these variables. For students who do not receive the review session, there is a strong positive relationship between mathematics ability and

performance on the statistics examination. However, the review session has a compensatory effect for weaker students. When students receive a review session, there is a much-reduced relationship between mathematics ability and performance; the weaker students ‘catch up’ with the stronger students. Put another way, the effect of mathematics ability on performance is conditional on whether or not the instructor provides a review session. An introduction to the categorical by continuous variable interaction is given in [1] with an extensive treatment in [10].

Continuous by Continuous Variable Interactions

Finally, two or more continuous variables may interact. Suppose we have a continuous measure of motivation to succeed. Motivation may interact with mathematics ability, as shown in Figure 2(b). The relationship of ability to performance is illustrated for three values of motivation along a motivation continuum. The effect of ability becomes increasingly more positive as motivation increases – with low motivation, ability does not matter. The effect of ability is conditional on the strength of motivation; put another way, motivation moderates the relationship of ability to performance.

Both continuous by continuous and continuous by categorical interactions are specified and tested in the **multiple linear regression** (MR) framework. In MR, the regression of performance on mathematics ability at one value of motivation is referred to as a *simple regression*, analogous to a simple main effect in ANOVA. In Figure 2(b), we have three simple regression lines for the effects of ability on performance, each at a different value of motivation. A complete treatment of interactions in the multiple regression framework, with prescriptions for probing and interpreting interactions involving continuous variables, is given in [1]; see also [2, 4].

Figure 2 Interactions involving continuous variables. (a) Categorical by continuous variable interaction. (b) Continuous by continuous variable interaction

Types of Interactions by Pattern

Patterns of interactions are characterized in a variety of ways, regardless of the combination of categorical and continuous variables comprising the interaction. We consider two such categorizations: (a) crossover versus noncrossover interactions, and (b) synergistic versus buffering interactions versus compensatory interactions.

Crossover versus Noncrossover Interactions

Crossover interactions (or *disordinal interactions*) are ones in which the direction of effect of one variable reverses as a function of the variable with which it interacts. Figure 1(b) illustrates a crossover interaction. With no study guide, performance is superior with the review session; with a study guide, performance is superior without a review session. *Non-crossover interactions* (or *ordinal interactions*) are ones in which the direction of effect of one variable is constant across the values of the other variable with which it interacts. Both interactions in Figure 2 are noncrossover interactions. In Figure 2(b), performance is always higher for higher motivation across the range of ability.

Synergistic versus Buffering Interactions versus Compensatory Interactions

Synergistic interactions are ones in which two variables combine to have a joint effect that is even greater than the sum of the effects of the variables. In Figure 2(b), performance increases with ability; it increases with motivation. There is a synergy between ability and motivation – being high on both produces superb performance. *Buffering interactions* are ones in which variables are working in opposite directions, and the interaction is such that the effect of one variable weakens the effect of the other variable. Suppose we assess the number of other demands on students when they are studying for an exam. As other demands increase, performance is expected to decrease due to lack of study time. However, the study guide buffers or weakens the impact of other demands on performance by making studying much more focused and efficient. We would say that the use of the study guide buffers the negative effect of other demands. *Compensatory (or interference) interactions* are those in which both variables have an effect in the same direction, but in which one variable compensates for the other, an ‘either-or’ situation. Figure 2(a) illustrates such an interaction. Both ability and the review session have a positive effect on

performance; however, the review session weakens the positive effect of ability.

Interactions Beyond the ANOVA and Multiple Regression Frameworks

The specification and testing of interactions extends to the **generalized linear model**, including **logistic regression** [3], to hierarchical linear models [7] (see **Linear Multilevel Models**), and to structural equation modeling [9].

Interaction Plot

An interaction plot is a graphical tool for examining the interactions or dependencies between variables (factors) in designed experiments. Its most common role is to help with the interpretation of results from an **analysis of variance (ANOVA)**, but it can also be used as an exploratory device for determining whether an additive or interaction model is appropriate (*see Interaction Effects*).

An interaction plot for, say, a two-factor experimental design is an x–y line plot of cell (level combination) means on the response variable for each level of one factor over all the levels of a second factor. Thus, if the lines or profiles corresponding to the separate factor levels are parallel, that is, no differential effect over different combinations of the levels of the factors is revealed, then there is no interaction. If they are not parallel, then an interaction is present. Of course, since the cell means are sample means, we have to exert a degree of commonsense in what we declare as parallel and nonparallel.

Figures 1(a–c) illustrate some possible patterns for a two-factor design in which Factor A has three levels and Factor B has two levels. In Figure 1(a) we have parallel lines because the distance between the cell means for levels B1 and B2 of Factor B is essentially the same whichever level of Factor A we are looking at, that is, there is no interaction. By contrast, in Figures 1(b) and 1(c) the differences between the means vary over the levels of A, so the lines are not parallel and we conclude that there is an interaction. However, note that in Figure 1(b) the means for B1 are always greater than for B2; an interaction of this type is sometimes described as ‘ordinal’. On the other hand, in Figure 1(c), we have a crossover at A1 indicating a ‘disordinal’ interaction.

When there are three or more factors in the design, the number of graphs required becomes more unwieldy and the interpretation correspondingly more difficult. For instance, to investigate the first- and second-order interactions in a three-factor design, we would need a plot for each of the three pairs of factors, and then a sequence of plots for two of the factors at each level of the third.

Statistical packages such as SPSS and Minitab offer interaction plots as options for their ANOVA

Figure 1 (a) No interaction; (b) ordinal interaction; (c) disordinal interaction

or **generalized linear model (GLM)** (*see Software for Statistical Analyses*) procedures.

Internal Consistency

Internal consistency usually refers to the degree to which a set of items or measures are all indicators of a single construct or concept. Arithmetically, internal consistency is usually evaluated by assessing the degree to which the items in a measure correlate or covary highly with each other or with the total of the scores or responses in the remainder of the measure. Related notions are that of test homogeneity, again the degree to which items in a measure are indices of the same construct and unidimensionality, which also refers to the degree to which items measure a single construct.

Internal consistency, homogeneity, and unidimensionality are often used interchangeably when referring to a test and the interrelationships between the items comprising the test. Hattie [1] provided a review of 30 different methods of determining or assessing unidimensionality. Those investigators who focus on unidimensionality have usually proposed an index on the basis of **factor analysis** or **principal component analysis**. In these cases, a perfectly internally consistent measure would be that in which the first factor or component accounts for all the covariation between items. Those who focus on the reliability of items will usually focus on some version of coefficient alpha (see below) or the average correlation or covariance between items designed to measure a single construct. Still others will examine the pattern of responses across items. Obviously, the manner in which internal consistency or unidimensionality is operationalized varies with the investigator. Not often discussed in quantitative treatments of internal consistency is the obvious requirement that all items measure conceptually similar content.

Coefficient alpha is perhaps most often considered an index of internal consistency, though technically many would hold that its calculation involves an assumption of unidimensionality rather an index of it. Coefficient alpha is the ratio of the product of the squared number of items in a measure and the average covariance between items in it to the total variance in the measure. Formally,

$$\text{Alpha} = \frac{n^2(\text{average cov}_{ij})}{\sigma^2}, \quad (1)$$

where n is the number of items in the measure, cov_{ij} is the covariance between items i and j , and σ^2 is the variance of the test. In standardized terms, this index is the ratio of the product of the squared number of items in the measure and the average correlation among items in it divided by the sum of the correlations among all items in the test including the correlations of items with themselves. Formally, this is similar to the unstandardized version of alpha:

$$\text{Standardized alpha} = \frac{n^2(\text{average cor}_{ij})}{R}, \quad (2)$$

where n is the number of items in the measure, cor_{ij} is the correlation between items i and j , and R is the sum of the correlations among the items including elements above and below the diagonal as well as the diagonal 1.00s. Theoretically, this ratio is based on the notion that if items in a measure are all indices of the same construct, they should correlate perfectly. Correlations between items are usually less than 1 (likewise, covariances between items do not approach the variances of the items involved), and the difference between diagonal elements and off-diagonal elements in an item intercorrelation matrix is treated as error or lack of internal consistency reliability.

The problem with considering coefficient alpha as an index of internal consistency is that with a large number of items, the ratio referred to above can yield a relatively high value even though there is evidence that items measure more than one construct. This would be the case when there are clusters of items that are relatively highly correlated with each other but not highly correlated with items in other clusters in the test [2]. In this case, coefficient alpha might indicate high internal consistency, while an observation of the correlations among the items or a factor analysis of the items would lead a researcher to conclude that more than one construct is accounting for the between-item covariances.

So internal consistency should be indicated by relatively high intercorrelations between items with little or no variability in the intercorrelations or item covariances. Any variability (apart from variability that can be accounted for by sampling error) in item covariances or item intercorrelations is evidence that more than one construct is being measured. Also, the very obvious, but often ignored, condition is

2 Internal Consistency

that all items in the measure address conceptually similar content.

Internal Validity

Campbell and Stanley [1] made a two-part distinction between internal validity, which referred to the question of whether the data for a particular study justified drawing the conclusion that there was a relationship between the independent and dependent variable, and whether it was causal, and **external validity**, which referred to the degree to which the results of this experiment would generalize to other populations, settings, and variables. Cook and Campbell [2] and Shadish et al. [3] carried these distinctions further. They added statistical conclusion validity, which referred to whether the statistical conclusions were appropriate to establish that the variables covaried, and separated that from internal validity, which dealt with whether this covariance could be given a causal interpretation.

Suppose, for example, that an experimental and control group were found to differ with respect to a measure of self-esteem. If the difference between the groups was significant, but the data strongly violated the assumption of normal distribution of errors, then the statistical conclusion validity of the experiment could be compromised. If we subsequently learn that the experimental group consisted of all girls, and the control group contained all boys, we would be forced to admit that any difference that resulted could as easily be attributed to gender differences as to the experimental treatment. Such a study would be lacking in internal validity. Campbell and Stanley referred to internal validity as the *sine qua non* of interpretability of experimental design.

Campbell and Stanley [1] popularized eight different classes of extraneous variable that can jeopardize internal validity. Others have added additional classes over time. The following list is based on the nine different classes proposed by Shadish et al. [[3]]. Shadish et al. presented experimental designs that address threats from each of these sources of invalidity; those designs are given only slight reference here. Additional information can be obtained from the references and from several excellent sites on the Internet.

Threats to Internal Validity

There are at least 14 sources of threat to internal validity. They include the following:

- Ambiguous temporal precedence
 - A basic foundation of imputing a causal effect is that the cause must precede the effect (*see Hill's Criteria of Causation*). When data are collected in such a way that temporal priority cannot be established (e.g., in a cross-sectional study), our ability to indicate the direction of cause is compromised, and the internal validity of the study is compromised.
- Selection
 - This threat refers to differences between the two groups in terms of participant assignment. Unless participants are assigned at random to conditions, any resulting differences might be attributable to preexisting group differences rather than to the treatment itself.
- History
 - Differences between pre- and posttesting could be attributable to any event that occurred between the two treatments in addition to an experimental intervention. This threat can often be addressed by including a randomly assigned control group that is assessed for pre- and posttest measures, but does not receive the treatment. Presumably, that group is as likely as the experimental group to be affected by historical events, and any *additional* effect in the treatment group would represent the introduction of treatment.
- Maturation
 - Maturation refers to any changes in the participants as a result of the passage of time. If, for example, participants judged the desirability of cookies before and after a lecture on nutrition, the passage of time, and the resulting increase in hunger, might have an important effect on the outcome, independent of any effect of the lecture. Appropriate compensatory designs include a group that experiences the same maturation opportunity but not the intervention.
- Regression to the Mean
 - When groups are selected on the basis of extreme scores, differences on a subsequent measure could reflect statistical **regression to the mean**. For example, if we select the worst students in the class and provide additional tutoring, later scores may show an improvement that cannot be unequivocally attributed to our intervention. Someone scoring very

2 Internal Validity

- poorly on one test is much more likely to score better, rather than worse, on a subsequent test. Here again pre- and posttest scores from an untreated control group provide an opportunity to partial out change attributable to regression to the mean.
- Attrition or Experimental Mortality
 - Differential participant **attrition** for two or more groups can produce differences between treatments that are attributable to the attrition rather than to the treatments. Suppose that after an initial test, participants are split into two groups, one receiving special tutoring and the other assigned to watch a video. Some of those watching the video may become bored because of a short attention span and as a result, engage in behavior that results in their being expelled from the study. Any subsequent differences between treatment groups may be due to higher average attention span in the remaining members of the control group.
 - Repeated Testing
 - The effect of having taken one test on the scores that result from a subsequent test. For example, the common belief that repeated practice with the SAT exam leads to better test-taking skills would suggest that a second administration of the SAT would lead to higher scores, independent of any gain in actual knowledge.
 - Instrumentation
 - Instrumentation refers to the change in calibration of an instrument over time. While we normally think of this as applying to instruments taking physical measurement, such as a scale or meter, it applies as well to paper and pencil tests or human scorers who no longer measure the same thing that they measured when the test was developed.

- Interaction of threats
 - Each of the preceding threats may interact with any of the other preceding threats. Suppose, for example, that the control group is comprised of mostly preadolescent males, while participants in the experimental group have just entered adolescence. We might anticipate a greater maturational change between the pretest and posttesting in the experimental group than we would in the control group. This makes it impossible to clearly assign any differences we observe to the effect of our treatment.

For other threats to invalidity, *see* **Reactivity**, **Expectancy Effect by Experimenters**, **Demand Characteristics**, and **Hawthorne Effect**. For approaches to dealing with these threats, *see* **Nonequivalent Group Design**, **Regression Discontinuity Design**, and, particularly, **Quasi-experimental Designs**.

Internet Research Methods

The Internet and the World Wide Web have dramatically changed the ways in which research is conducted. New tools, such as on-line information directories and search engines, have made finding information faster and more efficient than browsing library stacks that once characterized much research. Networked computers and related software provide a means for presenting stimuli and questions to respondents in many different places, often in real time. The Internet has reduced the spatial and temporal boundaries that once limited both the ready availability of extant information and the ability to gather new information. Information is posted and maintained on the Internet by government organizations, commercial businesses, universities, news organizations, research laboratories, and individuals, among others. Part of the power of the World Wide Web is that it makes such information readily accessible in a common format to any user. Text, images, audio, and video are all available on the Web.

The power of the Internet is not without its costs, however. The amount of information that is available on the Internet is daunting. A simple search can produce thousands of 'hits' that appear to be relevant. Links from one information site to another can greatly expand the scope of information searches. Distilling and integrating the volumes of information produced in a search is a significant task. Ideally, a researcher would attempt to narrow a search to only the most relevant sources, but the relevance of information is not always obvious. Even when information is narrowed in scope, there are questions about the credibility and reliability of the information. Thus, while it may appear that the Internet has taken much of the work out of finding information, the reality is not so simple. Finding information is easier and faster on the Internet, but the real work of evaluating, interpreting, and integrating such information, which is the goal of research, is as difficult as ever.

This article provides an introduction to the use of the Internet as a research tool and a brief overview of research tools and sources. The article also provides references for further exploration of information on the Internet, and for discussion of the evaluation

and use of information and data obtained from the Internet.

Two Types of Research

Secondary Research

Secondary research uses data and information collected by others and archived in some form. Such information includes government records and reports, industry studies, archived data, and specialized information services, as well as digitized versions of books and journals found in libraries. Much of the information that is accessible on the Internet is secondary information. Secondary information takes a variety of forms and offers relatively quick and inexpensive answers to many questions. It may be little more than a copy of a published report or it may involve a reanalysis of original data. For example, a number of syndicated research providers obtain government data, such as that obtained by the Census Bureau, and develop specialized reports, provide data access capabilities, or combine data from multiple sources. Several syndicated research providers obtain electronic scanner information from retailers and provide reports on the sales, prices, and other features of retail products. Other syndicated research providers collect information about product awareness, product preference, and customer satisfaction for entire industries. Similarly, some organizations offer reports of large-scale tracking studies of political trends, media usage habits, lifestyles, and purchasing habits. Table 1 provides a listing of representative Web sites that provide secondary information and data.

Secondary research generally offers a faster and less expensive means for obtaining information than collecting new data. Data and reports are already available, so they often can be obtained immediately. However, secondary research may not provide the specific information required for a researcher's purpose, and it may not be as up-to-date as would be desirable.

Much of the research that takes place on the Internet involves the use of tools, such as directories and search engines, to identify secondary sources of information. Directories are lists of resources arranged by subject that have been created for the specific purpose of organizing information content. Much like the table of contents

2 Internet Research Methods

Table 1 Useful secondary sources of information on the internet

Census Bureau (http://www.census.gov) Site of the United States Census Bureau with links to comparable sites in other countries.	Economist Intelligence Unit (http://store.eiu.com) Source of international information provided by the publisher of <i>The Economist</i> .

of a book, a directory provides a list of topics contained within a data source. Perhaps the best known and largest directory on the Internet is Yahoo (<http://www.yahoo.com>). Other common directories include Hotbot (<http://www.lycos.hotbot.com>), Looksmart (<http://www.looksmart.com>), Galaxy (<http://www.Galaxy.com>) and the Librarians' Index to the Internet (<http://www.lii.org>). Directories are especially useful research tools when the researcher has identified a general area of interest and wishes to take advantage of the organizational structure provided by a directory. Also, use of a directory narrows the content, and that can make finding information more efficient. In contrast to directories, search engines provide a means for doing keyword searches across the Internet. They are most useful when the researcher needs specific information found in many sources and across many different directories. Search engines differ in the way they search the Internet and the way they organize the results of the search. Among the better known search engines are Google (<http://www.google.com>), All the Web (<http://www.alltheweb.com>), Alta Vista (<http://www.altavista.com>), and Lycos (<http://www.lycos.com>). Sometimes, a researcher will find it useful to search multiple directories and/or search engines simultaneously. Metasearch tools such as Proteus Internet Search

(<http://www.thrall.org/proteus.html>), Ixquick (<http://www.ixquick.com>), Metacrawler (<http://www.metacrawler.com>), and Dogpile (<http://www.dogpile.com>) are useful for such broad searches.

The use of directories and search engines can produce quick results. Such searches may also produce many irrelevant or out-of-date sources. For this reason, experienced researchers tend to identify and bookmark those Web sites that they find most useful and to which they return again and again.

Primary Research

The Internet also can be used for conducting primary research, that is, for obtaining data in the first instance. Primary research involves the design of research and the collection and analysis of data that address specific issues identified by the researcher. While there are many different types of primary research, most primary research can be classified as either qualitative or quantitative. **Qualitative research** is most useful for generating ideas, for generating diagnostic information, and for answering questions about why something is happening. Individual interviews and focus groups are two of the more common qualitative research techniques, and

Table 2 Representative tools for conducting research on the internet**SurveyMonkey** (<http://www.surveymonkey.com>)

A tool for designing and conducting on-line survey research. Free for surveys involving up to 10 items and 100 respondents.

Zoomerang (<http://info.zoomerang.com>)

Another on-line survey research tool. Provides templates for more than a 100 common types of surveys and preconstructed panels of potential respondents with known characteristics.

SurveySite (<http://www.surveysite.com>)

Web site for a commercial provider of on-line focus groups and other on-line research tools.

E-Prime (<http://www.pstnet.com>)

A software package published by Psychology Software Tools, Inc. that enables the design and administration of behavioral experiments on-line.

both are now routinely conducted via the Internet. The interactive nature of the Internet with threaded discussions, chatrooms, and bulletin boards provides an ideal venue for the dialog that characterizes qualitative research. Quantitative tools, which include surveys, are most useful for obtaining numeric summaries that can be used to characterize larger populations. On-line surveys have become ubiquitous on the Web and provide a means for obtaining current information from survey respondents.

The Internet provides a powerful means for conducting primary behavioral research. The Internet can be used to present stimulus materials to respondents ranging from text to audio to streaming video. The respondents can be asked to respond immediately. Stimulus materials are easily customized with a computer. Hence, it is easy to construct alternative treatment conditions and scenarios for the conduct of on-line experiments. Specialized software has been developed to facilitate the conduct of both qualitative and quantitative research on the Internet. Table 2 provides a brief description of representative types of such software.

Evaluating Research on the Internet

Not all information on the Internet is equally reliable or valid. Information must be evaluated carefully and weighted according to its recency and credibility. The same questions that arise in the evaluation of secondary sources also arise in the context of primary research. The only difference is that these questions must be addressed retrospectively for secondary research, while they must be addressed prospectively for primary research. When evaluating information, six questions must be answered: (a) What was (is) the

purpose of the study? (b) Who collected (or will collect) the information? (c) What information was (will be) collected? (d) When was (will) the information (be) collected? (e) How was (will) the information (be) obtained? (f) How consistent is the information with other sources? In answering these basic questions, other more specific questions will arise. These more specific questions include the source(s) of the data, measures used, the time of data collection, and the appropriateness of analyses and conclusions.

Summary

The Internet provides powerful tools for obtaining data. However, it is always necessary to carefully evaluate the information. There are numerous comprehensive treatments of the use of the Internet as a research tool [1–3]. It is important to recognize that the Internet has brought with it some unique challenges, including concerns about its intrusiveness, invasion of individuals' privacy, and its appropriate use with children [4]. The Internet is a tool for efficiently obtaining information but its power assures that it will yield a great deal of irrelevant and unreliable information. The researcher's task is to determine how to best use the information.

Interquartile Range

The interquartile range (IQR) is a measure of spread defined as the range of the middle 50% of scores in an ordered set of data, that is, the difference between the upper **quartile** (Q_3) and the lower quartile (Q_1). For example, if Q_3 were 25 and Q_1 were 5, then the IQR would be 20.

As with other measures that are based on quartiles, such as the median, the IQR has the advantage that it is little affected by the presence of extreme scores. In a **box plot**, it is represented by the length of the box and is sometimes referred to as the H-range [1] or the midspread.

As an example, assume data from a normal distribution on the number of arithmetic problems solved by 12 children. These data are 11 10 12 12 12 14 14 15 17 17 18 19, and have a mean of 14.17, and a standard deviation of 3.07. $Q_1 = 12$ and $Q_3 = 17$, so the interquartile range is 5.0.

If the data had been slightly more spread in the tails, we might have 6 8 12 12 12 14 14 15 17

19 21 23 Here the mean is still 14.17, the standard deviation has increased by nearly 2/3 to 5.0, and the interquartile range has increased only slightly to 6.0.

Finally, if we have one extreme score, giving us data values of 6 8 12 12 12 14 14 15 17 19 21 33, The mean will increase to 15.25 (the median would have remained constant), the standard deviation would increase to 7.0, while the interquartile range would remain at 6.0.

Dividing the IQR by 2 produces the semi-interquartile range (sometimes known as the quartile deviation). The semi-interquartile range is an appropriate measure of spread to quote when reporting medians.

Interrupted Time Series Design

The interrupted time-series design [2] provides a method for researchers to examine the effect of an intervention on a single case, where the case may be a group or an individual. The basic interrupted time-series design is diagrammed in Figure 1, which shows there are multiple observations both prior to and after the intervention. A graph, showing an example of the kind of data obtained from an interrupted time-series design is also provided in Figure 1. The points represent observations, the solid lines are trend lines, and the dotted line is a projection from baseline. The difference between the dotted line and the post intervention solid line provides an estimate of treatment effect.

Discussion of the interrupted time-series design occurs both in the literature dealing with **quasi-experimental designs** [6] and the literature dealing with **single-case designs** [5]. In the single-case design literature, the basic interrupted time-series design is often referred to as an AB design, where the time prior to the intervention makes up the baseline phase (A) and the time after the intervention makes up the treatment phase (B). Although the form of the design remains the same, the applications used to characterize the design differ considerably between the quasi-experimental and single-case literatures.

Applications

Applications of interrupted time-series designs used to illustrate quasi-experiments often focus on archival

data that contain an aggregate value for a group across a large number of time points – for instance, research examining the frequency of behavior before and after a policy implementation. Specifically, one might be interested in the frequency of fatal motorcycle accidents before and after a mandatory helmet law was implemented. Another example would be to examine the frequency of behaviors before and after a major event. Specifically, one might be interested in teacher morale before and after the introduction of a new principal at their school.

Applications of interrupted time-series designs in the single-case literature tend to focus on the behavior of a single participant in a context where the researcher has some level of control over the measurement process, the observational context, and decisions about when to intervene – for example, research examining the effects of the introduction of some kind of treatment. In particular, one might be interested in measuring the aggressive behavior of a child before and after the introduction of therapy. Similarly, one might be interested in measuring the drug behavior of someone before and after treatment in a drug facility.

Types of Treatment Effects

Treatment effects can vary greatly from application to application in both their magnitude and their form. Figure 1 shows a treatment effect that remains constant over time, which is characterized by an immediate (or abrupt) upward shift in level but no change in slope. Figure 2 illustrates a variety of different treatment effects. Figures 2(a, c, e, and f), all show immediate effects, or discontinuities in the time series at the time of intervention.

Figure 1 Diagram of an interrupted time-series design where O s represent observations and the X represents the intervention (left panel), and graphical display of interrupted time-series data (right panel)

2 Interrupted Time Series Design

Figure 2 Illustration of different types of effects that may be found using an interrupted time-series design: immediate change in level (a), change in slope (b), a change in both level and slope (c), a delayed change in level (d), a transitory effect (e), and an effect that diminishes over time (f)

Figure 2(a), like Figure 1, shows a constant effect, while Figures 2(c, e, and f) show effects that change over time. In Figure 2(c) the effect becomes larger over time, whereas in Figures 2(e and f) the effect diminishes over time. In Figure 2(e), the effect may be referred to as transitory because there appears to be no effect by the end of the time series. For Figures 2(b and d), there is no immediate shift and thus it takes longer before a treatment effect is observed. In Figure 2(b) the treatment effect gradually increases over time, while in Figure 2(d) the treatment effect is delayed.

Design Issues

Number of Observations

The number of observations within a time series varies greatly across applications. While some studies have over 100 observations, others contain fewer than 10. Generally speaking, greater numbers of observations lead to stronger statements about treatment effects, and allow for more flexibility in analyzing the data. The number of observations needed, however, depends greatly on the application. A researcher

facing substantial variation around the trend lines will need a large number of observations to make a precise inference about the size of the treatment effect. In contrast, a researcher who encounters no variation in the baseline data may be able to infer a positive treatment effect with relatively few observations.

Baseline Variability

In the single-case literature, where the number of observations tends to be smaller, researchers often work to actively reduce the variability around their trend lines. For example, the researcher may notice a baseline variation that is associated with the time of day the observation is made, the particular activity being observed, and the people present during the observation. Under these circumstances, the researcher could reduce variation by moving toward greater commonality in the experimental conditions. There may also be inconsistencies in how the observations are rated, stemming from the use of different observers on different days or an observer who has ratings that tend to drift over time. In these circumstances, it may be possible to provide training to reduce the variability. In situations in which the researcher has control over the study, it is often possible to reduce variability, making it possible to make effect inferences from relatively short interrupted time-series studies. In situations in which the researchers do not have this much control, they may still work to identify and measure variables associated with the variability. This additional information can then be taken into account during the analysis.

Threats to Validity

When effect inferences are made, researchers often consider alternative explanations for why there may have been a change in the time series. Put another way, they consider threats to the validity of their inferences (*see* **Validity Theory and Applications; Internal Validity; External Validity**). It is possible, for example, that some other event occurred around the same time as the intervention and this other event is responsible for the change. It is also possible that a child happened to reach a new developmental stage, and this natural maturation led to the observed

changes in behavior; or that the instrumentation changed, leading to the observed change. Researchers may choose to add design elements to the basic interrupted time-series design to reduce the plausibility of alternative explanations. Doing so leads to more complex interrupted time-series designs.

More Complex Interrupted Time-series Designs

One option would be to remove the treatment from the participants, which is referred to as a **reversal design** (or withdrawal design). The simplest reversal design, which is diagrammed in Figure 3, has multiple observations during an initial baseline phase (A), multiple observations in the treatment phase (B), and then multiple observations in a second baseline phase (A). If the series reverses back to baseline levels when the treatment is removed, it becomes more obvious that the treatment led to the changes. Put another way, history and maturation effects become less plausible as explanations for the observed change. It is also possible to extend the ABA design to include more phases, creating more complex designs like the ABAB or the ABABAB design.

Another common extension of the interrupted time-series design is **the multiple baseline design**. In the multiple baseline design, a baseline phase (A) and treatment phase (B) are established for multiple participants, multiple behaviors, or multiple settings. The initiation of the treatment phases is staggered across time, creating baselines of different lengths for the different participants, behaviors, or settings. A diagram for the two-baseline version of the design and a corresponding graphical display are presented in Figure 3. As the number of baselines increases, it becomes less likely that history or maturational effects would stagger themselves across time in a manner that coincided with the staggered interventions.

A third variation, Figure 3(c), is obtained by including a comparison series. The comparison series could come from a control group that does not receive the treatment, or it could include data from a nonequivalent dependent variable. It is also possible to combine several of these additional elements. For example, one could combine elements from the reversal and multiple baseline design.

Figure 3 Design diagram and graphical display of interrupted time-series designs incorporating a withdrawal of the treatment (a), multiple baselines (b), and a comparison series (c). The O s represent observations, X represents the implementation of the intervention, and the X^- represents removal of the intervention

Analysis of Interrupted Time-series Data

Researchers typically start by visually analyzing a graph of the data. Additional analyses depend on the goals of the researcher, the variability in the data, and the amount of data available. Those interested in making inferences about the size and form of the treatment effect may consider selecting from a variety of statistical models for time-series data. Different models allow estimation of different types of treatment effects. For example, a model could contain one parameter for the level before treatment and one parameter for the change in level that occurs with the intervention. Such a model makes sense for a treatment effect that leads to an immediate shift in level, like the effect shown in Figure 1. As the effects become more complicated, additional

parameters need to be included to fully describe the treatment effect [4].

Statistical models for time-series data also differ in how the errors are modeled, where errors are the deviations of the observations from the trend lines that best fit the time-series data. The simplest model would result from assuming the errors were independent, which is what is assumed if one uses a standard regression model. There is reason, however, to suspect that the errors will often not be independent in time-series data. We often anticipate that unaccounted for factors may influence multiple consecutive observations. For example, a child's behavior may be affected by being sick, and being sick could be an unaccounted for factor that influenced observations across multiple days in the study. Under these circumstances, we expect that

errors that are closer in time will be more similar than errors further apart in time. Consequently, researchers often turn to statistical models that allow for dependencies, or autocorrelation, in the error structure [1].

Dependent error models differ in complexity. A researcher with relatively few observations will often have to assume a relatively simple model for the errors, while researchers with larger numbers of observations may use the data to help select from a wide range of possible models. Uncertainties that arise about the appropriateness of assuming a statistical model for the time-series data can lead to consideration of alternative approaches for analyzing the data.

Randomization tests [3] provide an alternative for researchers who wish to test the no-treatment-effect hypothesis without assuming a model for the data. The logic of randomization tests requires researchers to incorporate randomization in their designs. For example, they could randomly select the intervention point from among possible intervention points. A variety of randomization schemes and tests have been developed, and generally more statistical power is obtained for more complex designs.

Intervention Analysis

When a time series is recorded over an extended time interval $\{1, 2, \dots, n\}$, it frequently happens that, at some known time T in the interval, an event occurs that causes long-term or short-term changes in level of the series. For example, a change in the tax laws may have a long-term effect on stock returns, or the introduction of seat-belt legislation may have a long-term effect on the rate of occurrence of serious traffic injuries, while a severe storm in a particular city is likely to increase the number of insurance claims for a short period following the storm.

To account for the possible patterns of change in level of a time series $\{Y_t\}$, Box and Tiao [4] introduced the following model, in which it is assumed that the time T at which the change (or “intervention”) occurs is known:

$$Y_t = \sum_{j=0}^{\infty} \tau_j x_{t-j} + N_t, \quad (1)$$

where $\{N_t\}$ is the undisturbed time series (that can very often be modeled as an ARMA or ARIMA process), $\{\tau_j\}$ is a sequence of weights, and the “input” sequence $\{x_t\}$ is a deterministic sequence, usually representing a unit impulse at time T or possibly a sequence of impulses at times $T, T+1, T+2, \dots$, that is,

$$x_t = \begin{cases} 1, & \text{if } t = T, \\ 0 & \text{otherwise,} \end{cases} \quad (2)$$

or

$$x_t = \begin{cases} 1, & \text{if } t \geq T, \\ 0 & \text{otherwise,} \end{cases} \quad (3)$$

respectively. (Other deterministic input functions $\{x_t\}$ can also be used, representing for example impulses at times T_1 and T_2 .) By selecting an appropriate input sequence and a parametric family of weights, $\tau_j(\omega)$, $j = 0, 1, 2, \dots$, where ω is a finite-dimensional parameter vector, the problem of fitting the model (1) becomes that of estimating ω and finding an appropriate ARMA or ARIMA model for the series $\{N_t\}$ (see **Time Series Analysis**).

For example, if it is believed that the effect on the number of insurance claims following a major storm at time $T-1$ will be the addition of new claims at times $T, T+1, T+2, \dots$, with

the numbers declining geometrically as time goes by, then the intervention term $\sum_{j=0}^{\infty} \tau_j x_{t-j}$ with x_t defined by (2) and $\tau_j = c\theta^j$ for some $c > 0$ and $\theta \in (0, 1)$ is appropriate. The contribution of the intervention term at time $T+j$ is then equal to $c\theta^j$, $j = 0, 1, 2, \dots$ and the problem of fitting the intervention model (1) is that of estimating the parameters c and θ , while simultaneously finding a suitable model for $\{N_t\}$. The weights in this case are members of a two-parameter family indexed by c and θ .

By allowing the weights to belong to a larger parametric family than the two-parameter family of the preceding paragraph, it is possible to achieve an extremely wide range of possible intervention effects. Box and Tiao proposed the use of weights τ_j that are the coefficients of z^j in the power series expansion of the ratio of polynomials $z^b w(z)/v(z)$, where b is a nonnegative integer (*the delay parameter*), and the zeroes of the polynomial $v(z)$ in the complex plane all have absolute values greater than 1. The intervention term can then be expressed as

$$\sum_{j=0}^{\infty} \tau_j x_{t-j} = \sum_{j=0}^{\infty} \tau_j B^j x_t = \frac{B^b w(B)}{v(B)} x_t, \quad (4)$$

where B is the backward shift operator and $B^b w(B)/v(B)$ is referred to as the *transfer function* of the filter with weights τ_j , $j = 0, 1, 2, \dots$. The geometrically decreasing weights of the preceding paragraph correspond to the special case in which the ratio of polynomials is $c/(1 - \theta z)$. The intervention model (1) with intervention term (4) is very closely related to the transfer function model of Box and Jenkins [3]. In the transfer function model, the deterministic input sequence $\{x_t\}$ is replaced by an observed *random* input sequence. In intervention modeling, the input sequence is *chosen* to provide a parametric family of interventions of the type expected. Having selected the function $\{x_t\}$ and the parametric family for the weights $\{\tau_j\}$, the problem of fitting the model (1) reduces to a nonlinear regression problem in which the errors $\{N_t\}$ constitute an ARMA or ARIMA process whose parameters must also be estimated. Estimation is by minimization of the sums of squares of the estimated white noise sequence driving $\{N_t\}$. For details, see, for example, [3], [4], or [5].

The goals of intervention analysis are to estimate the effect of the intervention as indicated by the term $\sum_{j=0}^{\infty} \tau_j x_{t-j}$ and to use the resulting model (1)

2 Intervention Analysis

for forecasting. For example, in [9], intervention analysis was used to investigate the effect of the American Dental Association's endorsement of Crest toothpaste on Crest's market share. Other applications of intervention analysis can be found in [1], [2], and [3]. A more general approach can also be found in [6], [7], and [8].

Example Figure 1 shows the number of monthly deaths and serious injuries on UK roads for 10 years beginning in January 1975. (Taking one month as our unit of time we shall write these as $D_t, t = 1, \dots, 120$. The data are from [7].) Seat-belt legislation was introduced in the UK in February, 1983 ($t = 98$), in the hope of reducing the mean of the series from that time onwards. In order to assess the effect of the legislation, we can estimate the coefficient θ in the model,

$$D_t = \sum_{j=0}^{\infty} \theta x_{t-j} + W_t, \quad t = 1, \dots, 120, \quad (5)$$

where x_t is defined by (3) with $T = 98$ and $D_t = W_t$ is the model for the data prior to the intervention. The intervention term in (5) can be expressed more simply as θf_t where $f_t = 0$ for $t \leq 97$ and $f_t = 1$ for $t \geq 98$. Figure 1 clearly indicates (as expected) the presence of seasonality with period 12 in $\{W_t\}$. If, therefore, we apply the differencing operator $(1 - B^{12})$ to each side of (5), we might hope to obtain a model for the differenced data, $Y_t = D_t - D_{t-12}, t = 13, \dots, 120$, in which the noise $\{N_t = W_t - W_{t-12}\}$ is representable as an ARMA process. Carrying out

Figure 1 Monthly deaths and serious injuries on UK roads, January 1975–December 1984

Figure 2 The differenced deaths and serious injuries on UK roads, showing the fitted intervention term

the differencing of the data, this does indeed appear to be the case. Our model for $\{Y_t\}$ is thus

$$Y_t = \theta \sum_{j=0}^{\infty} x'_{t-j} + N_t, \quad t = 13, \dots, 120, \quad (6)$$

where $\{x'_t\}$ is the differenced sequence $\{(1 - B^{12})x_t\}$, that is,

$$x'_t = \begin{cases} 1, & \text{if } 98 \leq t < 110, \\ 0 & \text{otherwise.} \end{cases} \quad (7)$$

The model (6) is now of the form (1) with $\{N_t\}$ representable as an ARMA process. For details of the least squares fitting of the model (6) to the differenced data, see [5], where it is found that the estimated value of θ is -362.5 (highly significantly different from zero) and a moving average model of order 12 is selected for $\{N_t\}$. Figure 2 shows the *differenced* data $\{Y_t\}$ together with the fitted intervention term in the model (6). The corresponding intervention term in the model (5) for the *original* data is a permanent level-shift of -362.5 .

Intraclass Correlation

Commonly used correlations such as the **Pearson product moment correlation** measure the bivariate relation between variables of different measurement classes. These are known as *interclass* correlations. By ‘different measurement classes’, we really just mean variables measuring different things. For example, we might look at the relation between attractiveness and career success; clearly one of these variables represents a class of measures of how good looking a person is, whereas the other represents the class of measurements of something quite different: how much someone achieves in their career. However, there are often cases in which it is interesting to look at relations between variables *within* classes of measurement. In its simplest form, we might compare only two variables. For example, we might be interested in whether anxiety runs in families, and we could look at this by measuring anxiety within pairs of twins (see [1]). In this case, the objects being measured are twins, and both twins are measured on some index of anxiety. As such, there is a pair of variables, which both measure anxiety and are, therefore, from the same class. In such cases, an intraclass correlation (ICC) is used and is commonly extended beyond just two variables to look at the consistency between judges. For example, in gymnastics, ice-skating, diving, and other Olympic sports, the contestant’s performance is often assessed by a panel of judges. There might be 10 judges, all of whom rate performances out of 10; therefore, the resulting measures are from the same class (they measure the same thing). The objects being rated are the competitors. This again is a perfect scenario for an intraclass correlation.

Models of Intraclass Correlations

There are a variety of different intraclass correlations (see [4] and [5]) and the first step in calculating one is to determine a model for your sample data. All of the various forms of the intraclass correlation are based on estimates of mean variability from a one-way **repeated measures Analysis of Variance (ANOVA)**.

All situations in which an intraclass correlation is desirable will involve multiple measures on different entities (be they twins, Olympic competitors, pictures,

sea slugs etc.). The objects measured constitute a random factor (see **Fixed and Random Effects**) in the design (they are assumed to be random exemplars of the population of objects). The measures taken can be included as factors in the design if they have a meaningful order, or can be excluded if they are unordered as we shall now see.

One-way Random Effects Model

In the simplest case, we might have only two measures (refer to our twin study on anxiety). When the order of these variables is irrelevant (for example, with our twin study it is arbitrary whether we treat the data from the first twin as being anxiety measure 1 or anxiety measure 2), the only systematic source of variation is the random variable representing the different objects. In this case, the only systematic source of variation is the random variable representing the different objects. As such, we can use a one-way ANOVA of the form:

$$x_{ij} = \mu + r_i + e_{ij}, \quad (1)$$

in which r_i is the effect of object i (known as the *row effects*), j is the measure being considered, and e_{ij} is an error term (the residual effects). The row and residual effects are random, independent, and normally distributed. Because the effect of the measure is ignored, the resulting intraclass correlation is based on the overall effect of the objects being measured (the mean between-object variability MS_{Rows}) and the mean within-object variability (MS_{W}). Both of these will be formally defined later.

Two-way Random Effects Model

When the order of measures is important, then the effect of the measures becomes important also. The most common case of this is when measures come from different judges or raters. Hodgins and Makarchuk [3], for example, show two such uses; in their study they took multiple measures of the same class of behavior (gambling) and also measures from different sources. They measured gambling both in terms of days spent gambling and money spent gambling. Clearly these measures generate different data so it is important to which measure a datum belongs (it is not arbitrary to which measure a datum

2 Intraclass Correlation

is assigned). This is one scenario in which a two-way model is used. However, they also took measures of gambling both from the gambler and a collateral (e.g., spouse). Again, it is important that we attribute data to the correct source. So, this is a second illustration of where a two-way model is useful. In such situations, the intraclass correlation can be used to check the consistency or agreement between measures or raters.

In this situation a two-way model can be used as follows:

$$x_{ij} = \mu + r_i + c_j + rc_{ij} + e_{ij}, \quad (2)$$

where c_j is the effect of the measure (i.e., the effect of different raters, or different measures), and rc_{ij} is the interaction between the measures taken and the objects being measured. The effect of the measure (c_j) can be treated as either a fixed effect or a random effect. How it is treated does not affect the calculation of the intraclass correlation, but it does affect the interpretation (as we shall see). It is also possible to exclude the interaction term and use the model:

$$x_{ij} = \mu + r_i + c_j + e_{ij}. \quad (3)$$

We shall now turn our attention to calculating the sources of variance needed to calculate the intraclass correlation.

Sources of Variance: An Example

Field [2] uses an example relating to student concerns about the consistency of marking between lecturers. It is common that lecturers obtain reputations for being ‘hard’ or ‘light’ markers, which can lead students to believe that their marks are not based solely on the

intrinsic merit of the work, but can be influenced by who marked the work. To test this, we could calculate an intraclass correlation. First, we could submit the same eight essays to four different lecturers and record the mark they gave each essay. Table 1 shows the data, and you should note that it looks the same as a one-way repeated measures ANOVA in which the four lecturers represent four levels of an ‘independent variable’, and the outcome or dependent variable is the mark given (in fact, these data are used as an example of a one-way repeated measures ANOVA).

Three different sources of variance are needed to calculate an intraclass correlation. These sources of variance are the same as those calculated in one-way repeated measures ANOVA (see [2] for the identical set of calculations!).

The Between-object Variance (MS_{Rows})

The first source of variance is the variance between the objects being rated (in this case the between-essay variance). Essays will naturally vary in their quality for all sorts of reasons (the natural ability of the author, the time spent writing the essay, etc.). This variance is calculated by looking at the average mark for each essay and seeing how much it deviates from the average mark for all essays. These deviations are squared because some will be positive and others negative, and so would cancel out when summed. The squared errors for each essay are weighted by the number of values that contribute to the mean (in this case, the number of different markers, k). So, in general terms we write this as:

$$SS_{\text{Rows}} = \sum_{i=1}^n k_i (\bar{X}_{\text{Row } i} - \bar{X}_{\text{all rows}})^2. \quad (4)$$

Table 1 Marks on eight essays by four lecturers

Essay	Dr Field	Dr Smith	Dr Scrote	Dr Death	Mean	S^2	$S^2(k-1)$
1	62	58	63	64	61.75	6.92	20.75
2	63	60	68	65	64.00	11.33	34.00
3	65	61	72	65	65.75	20.92	62.75
4	68	64	58	61	62.75	18.25	54.75
5	69	65	54	59	61.75	43.58	130.75
6	71	67	65	50	63.25	84.25	252.75
7	78	66	67	50	65.25	132.92	398.75
8	75	73	75	45	67.00	216.00	648.00
Mean:	68.88	64.25	65.25	57.38	63.94	Total:	1602.50

Or, for our example we could write it as:

$$SS_{\text{Essays}} = \sum_{i=1}^n k_i (\bar{X}_{\text{Essay } i} - \bar{X}_{\text{all essays}})^2. \quad (5)$$

This would give us:

$$\begin{aligned} SS_{\text{Rows}} &= 4(61.75 - 63.94)^2 + 4(64.00 - 63.94)^2 \\ &\quad + 4(65.75 - 63.94)^2 + 4(62.75 - 63.94)^2 \\ &\quad + 4(61.75 - 63.94)^2 \\ &\quad + 4(63.25 - 63.94)^2 + 4(65.25 - 63.94)^2 \\ &\quad + 4(67.00 - 63.94)^2 \\ &= 19.18 + 0.014 + 13.10 + 5.66 \\ &\quad + 19.18 + 1.90 + 6.86 + 37.45 \\ &= 103.34. \end{aligned} \quad (6)$$

This sum of squares is based on the total variability and so its size depends on how many objects (essays in this case) have been rated. Therefore, we convert this total to an average known as the *mean squared error (MS)* by dividing by the number of essays (or in general terms the number of rows) minus 1. This value is known as the *degrees of freedom*.

$$MS_{\text{Rows}} = \frac{SS_{\text{Rows}}}{df_{\text{Rows}}} = \frac{103.34}{n-1} = \frac{103.34}{7} = 14.76. \quad (7)$$

The mean squared error for the rows in Table 1 is our estimate of the natural variability between the objects being rated.

The Within-judge Variability (MS_W)

The second variability in which we are interested is the variability within measures/judges. To calculate this, we look at the deviation of each judge from the average of all judges on a particular essay. We use an equation with the same structure as before, but for each essay separately:

$$SS_{\text{Essay}} = \sum_{k=1}^p (\bar{X}_{\text{Column } k} - \bar{X}_{\text{all columns}})^2. \quad (8)$$

For essay 1, for example, this would be:

$$\begin{aligned} SS_{\text{Essay}} &= (62 - 61.75)^2 + (58 - 61.75)^2 \\ &\quad + (63 - 61.75)^2 + (64 - 61.75)^2 = 20.75. \end{aligned} \quad (9)$$

The degrees of freedom for this calculation is again one less than the number of scores used in the calculation. In other words, it is the number of judges, k , minus 1.

We calculate this for each of the essays in turn and then add these values up to get the total variability within judges. An alternative way to do this is to use the variance within each essay. The equation mentioned above is equivalent to the variance for each essay multiplied by the number of values on which that variance is based (in this case the number of Judges, k) minus 1. As such we get:

$$\begin{aligned} SS_W &= s_{\text{essay1}}^2(k_1 - 1) + s_{\text{essay2}}^2(k_2 - 1) \\ &\quad + s_{\text{essay3}}^2(k_3 - 1) + \dots + s_{\text{essayn}}^2(k_n - 1). \end{aligned} \quad (10)$$

Table 1 shows the values for each essay in the last column. When we sum these values we get 1602.50. As before, this value is a total and so depends on the number essays (and the number of judges). Therefore, we convert it to an average by dividing by the degrees of freedom. For each essay, we calculated a sum of squares that we saw was based on $k - 1$ degrees of freedom. Therefore, the degrees of freedom for the total within-judge variability are the sum of the degrees of freedom for each essay $df_W = n(k - 1)$, where n is the number of essays and k is the number of judges. In this case, it will be $8(4 - 1) = 24$.

The resulting mean squared error is, therefore:

$$MS_W = \frac{SS_W}{df_W} = \frac{1602.50}{n(k-1)} = \frac{1602.50}{24} = 66.77. \quad (11)$$

The Between-judge Variability (MS_{Columns})

The within-judge or within-measure variability is made up of two components. The first is the variability created by *differences* between judges. The second is the unexplained variability (error for want of a better word). The variability between judges is again calculated using a variant of the same equation that we have used all along, only this time we are interested in the deviation of each judge's mean from the mean of all judges:

$$SS_{\text{Columns}} = \sum_{k=1}^p n_i (\bar{X}_{\text{Column } i} - \bar{X}_{\text{all columns}})^2 \quad (12)$$

4 Intraclass Correlation

or

$$SS_{\text{Judges}} = \sum_{k=1}^p n_i (\bar{X}_{\text{Judge } i} - \bar{X}_{\text{all Judges}})^2, \quad (13)$$

where n is the number of things that each judge rated. For our data we would get:

$$\begin{aligned} SS_{\text{Columns}} &= 8(68.88 - 63.94)^2 + 8(64.25 - 63.94)^2 \\ &\quad + 8(65.25 - 63.94)^2 + 8(57.38 - 63.94)^2 \\ &= 554. \end{aligned} \quad (14)$$

The degrees of freedom for this effect are the number of judges, k , minus 1. As before, the sum of squares is converted to a mean squared error by dividing by the degrees of freedom:

$$MS_{\text{Columns}} = \frac{SS_{\text{Columns}}}{df_{\text{Columns}}} = \frac{554}{k-1} = \frac{554}{3} = 184.67. \quad (15)$$

The Error Variability (MS_E)

The final variability is the variability that cannot be explained by known factors such as variability between essays or judges/measures. This can be easily calculated using subtraction because we know that the within-judges variability is made up of the between-judges variability and this error:

$$\begin{aligned} SS_W &= SS_{\text{Columns}} + SS_E \\ SS_E &= SS_W - SS_{\text{Columns}}. \end{aligned} \quad (16)$$

The same is true of the degrees of freedom:

$$\begin{aligned} df_W &= df_{\text{Columns}} + df_E \\ df_E &= df_W - df_{\text{Columns}}. \end{aligned} \quad (17)$$

So, for these data we obtain:

$$\begin{aligned} SS_E &= SS_W - SS_{\text{Columns}} \\ &= 1602.50 - 554 \\ &= 1048.50 \end{aligned} \quad (18)$$

and

$$\begin{aligned} df_E &= df_W - df_{\text{Columns}} \\ &= 24 - 3 \\ &= 21. \end{aligned} \quad (19)$$

The average error variance is obtained in the usual way:

$$MS_E = \frac{SS_E}{df_E} = \frac{1048.50}{21} = 49.93. \quad (20)$$

Calculating Intraclass Correlations

Having computed the necessary variance components, we shall now look at how the ICC is calculated. Before we do so, however, there are two important decisions to be made.

Single Measures or Average Measures?

So far we have talked about situations in which the measures we have used produce single values. However, it is possible that we might have measures that produce an average score. For example, we might get judges to rate paintings in a competition on the basis of style, content, originality, and technical skill. For each judge, their ratings are averaged. The end result is still the ratings from a set of judges, but these ratings are an average of many ratings. Intraclass correlations can be computed for such data, but the computation is somewhat different.

Consistency or Agreement?

The next decision involves whether we want a measure of overall consistency between measures/judges. The best way to explain this distinction is to return to our example of lecturers and essay marking. It is possible that particular lecturers are harsh (or lenient) in their ratings. A consistency definition views these differences as an irrelevant source of variance. As such the between-judge variability described above (MS_{Columns}) is ignored in the calculation (see Table 2). In ignoring this source of variance, we are getting a measure of whether judges agree about the relative merits of the essays without worrying about whether the judges anchor their marks around the same point. So, if all the judges agree that essay 1 is the best and essay 5 is the worst (or their rank order of essays is roughly the same), then agreement will be high: it does not matter that Dr. Field's marks are all 10% higher than Dr. Death's. This is a consistency definition of agreement.

Table 2 Intraclass correlation (ICC) equations and calculations

Model	Interpretation	Equation	ICC for example data
<i>ICC for Single Scores</i>			
One-way	Absolute agreement	$\frac{MS_R - MS_W}{MS_R + (k - 1)MS_W}$	$\frac{14.76 - 66.77}{14.76 + (4 - 1)66.77} = -0.24$
Two-way	Consistency	$\frac{MS_R - MS_E}{MS_R + (k - 1)MS_E}$	$\frac{14.76 - 49.93}{14.76 + (4 - 1)49.93} = -0.21$
	Absolute agreement	$\frac{MS_R - MS_E}{MS_R + (k - 1)MS_E + \frac{k}{n}(MS_C - MS_E)}$	$\frac{14.76 - 49.93}{14.76 + (4 - 1)49.93 + \frac{4}{8}(184.67 - 49.93)} = -0.15$
<i>ICC for Average Scores</i>			
One-way	Absolute agreement	$\frac{MS_R - MS_W}{MS_R}$	$\frac{14.76 - 66.77}{14.76} = -3.52$
Two-way	Consistency	$\frac{MS_R - MS_E}{MS_R}$	$\frac{14.76 - 49.93}{14.76} = -2.38$
	Absolute agreement	$\frac{MS_R - MS_E}{MS_R + (MS_C - MS_E/n)}$	$\frac{14.76 - 49.93}{14.76 + (184.67 - 49.93/8)} = -1.11$

The alternative is to treat relative differences between judges as an important source of disagreement. That is, the between-judge variability described above (MS_{Columns}) is treated as an important source of variation and is included in the calculation (see Table 2). In this scenario, disagreements between the relative magnitude of judge's ratings matters (so, the fact that Dr Death's marks differ from Dr Field's will matter even if their rank order of marks is in agreement). This is an absolute agreement definition. By definition, the one-way model ignores the effect of the measures and so can have only this kind of interpretation.

Equations for ICCs

Table 2 shows the equations for calculating ICC on the basis of whether a one-way or two-way model is assumed and whether a consistency or absolute agreement definition is preferred. For illustrative purposes, the ICC is calculated in each case for the example used in this article. This should enable the reader to identify how to calculate the various sources of variance. In this table, MS_{Columns} is abbreviated to MS_C , and MS_{Rows} is abbreviated to MS_R .

Significance Testing

The calculated intraclass correlation can be tested against a value under the null hypothesis using a

standard F test (see **Analysis of Variance**). McGraw and Wong [4] describe these tests for the various intraclass correlations we have discussed; Table 3 summarizes their work. In this table, ICC is the observed intraclass correlation whereas ρ_0 is the value of the intraclass correlation under the null hypothesis. That is, it is the value against which we wish to compare the observed intraclass correlation. So, replace this value with 0 to test the hypothesis that the observed ICC is greater than zero, but replace it with other values such as 0.1, 0.3, or 0.5 to test that the observed ICC is greater than known values of small, medium, and large-effect sizes respectively.

Fixed versus Random Effects

I mentioned earlier that the effect of the measure/judges can be conceptualized as a fixed or random effect. Although it makes no difference to the calculation, it does affect the interpretation. Essentially, this variable should be regarded as random when the judges or measures represent a sample of a larger population of measures or judges that could have been used. In other words, the particular judges or measures chosen are not important and do not change the research question that is being addressed. However, the effect of measures should be treated as fixed when changing one of

6 Intraclass Correlation

Table 3 Significance test for intraclass correlations (Adapted from McGraw, K.O. & Wong, S.P. (1996). Forming inferences about some intraclass correlation coefficients, *Psychological Methods* **1**(1), 30–46.)

Model	Interpretation	<i>F</i> -ratio	<i>Df</i> 1	<i>Df</i> 2
<i>ICC for Single Scores</i>				
One-way	Absolute agreement	$\frac{MS_R}{MS_W} \times \frac{1 - \rho_0}{1 + (k - 1)\rho_0}$	$n - 1$	$n(k - 1)$
Two-way	Consistency	$\frac{MS_R}{MS_E} \times \frac{1 - \rho_0}{1 + (k - 1)\rho_0}$	$n - 1$	$(n - 1)(k - 1)$
	Absolute agreement	$\frac{MS_R}{aMS_C + bMS_E}$		
	In which;		$n - 1$	$\frac{(aMS_C + bMS_E)^2}{\frac{(aMS_C)^2}{k - 1} + \frac{(bMS_E)^2}{(n - 1)(k - 1)}}$
	$a = \frac{k\rho_0}{n(1 - \rho_0)}$			
	$b = 1 + \frac{k\rho_0(n - 1)}{n(1 - \rho_0)}$			
<i>ICC for Average Scores</i>				
One-way	Absolute agreement	$\frac{1 - \rho_0}{1 - ICC}$	$n - 1$	$n(k - 1)$
Two-way	Consistency	$\frac{1 - \rho_0}{1 - ICC}$	$n - 1$	$(n - 1)(k - 1)$
	Absolute agreement	$\frac{MS_R}{cMS_C + dMS_E}$		
	In which;		$n - 1$	$\frac{(cMS_C + dMS_E)^2}{\frac{(cMS_C)^2}{k - 1} + \frac{(dMS_E)^2}{(n - 1)(k - 1)}}$
	$c = \frac{\rho_0}{n(1 - \rho_0)}$			
	$b = 1 + \frac{\rho_0(n - 1)}{n(1 - \rho_0)}$			

the judges or measures would significantly affect the research question (see **Fixed and Random Effects**). For example, in the gambling study mentioned earlier it would make a difference if the ratings of the gambler were replaced: the fact the gamblers gave ratings was intrinsic to the research question being addressed (i.e., do gamblers give accurate information about their gambling?). However, in our example of lecturers' marks, it should not make any difference if we substitute one lecturer with a different one: we can still answer the same research question (i.e., do lecturers, in general, give inconsistent marks?). In terms of interpretation, when the effect of the measures is a random factor then the

results can be generalized beyond the sample; however, when they are a fixed effect, any conclusions apply only to the sample on which the ICC is based (see [4]).

Intrinsic Linearity

When a response variable is related to one or more predictor variables in a nonlinear model (see **Nonlinear Models**), parameter estimation must be accomplished through a complicated, iterative process. In some cases, a transformation can be used to change the model to a linear one, thereby permitting analysis using the highly developed, efficient methods of linear models (see **Least Squares Estimation; Multiple Linear Regression**). In the classic linear model $Y = X\beta + \varepsilon$, parameter estimates are found through the familiar closed-form solution

$$\hat{\beta} = (X'X)^{-1}X'Y. \quad (1)$$

Some examples and the appropriate linearizing transformations are given below.

- (1) $Y = e^{\beta_0 + \beta_1 X_1 + \beta_2 X_2}$ is a nonlinear model, because it is not linear in the parameters. However, one can apply the natural logarithm (ln) transformation to both sides of the equation to obtain $\ln Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2$, which is a linear model with $\ln Y$ as the new response variable. One could say, then, that the model was intrinsically linear, but it appeared nonlinear because of an unfortunate choice of the response variable Y . Using $\ln(Y)$ instead makes all the difference.
- (2) $Y = \theta_1 X / (\theta_2 + X)$, the so-called Michaelis–Menten model, is also a nonlinear model. One can apply the reciprocal transformation to both sides of the equation to obtain

$$\frac{1}{Y} = \frac{\theta_2 + X}{\theta_1 X} = \frac{1}{\theta_1} + \frac{\theta_2}{\theta_1} \frac{1}{X}. \quad (2)$$

For clarity, this can be seen to be the form of a linear model $Z = \beta_0 + \beta_1 V$, with $Z = 1/Y$,

$$\beta_0 = \frac{1}{\theta_1}, \quad \beta_1 = \frac{\theta_2}{\theta_1}, \quad \text{and } V = \frac{1}{X}. \quad (3)$$

- (3) $Y = \alpha X^\beta e^{-\nu X}$. Take natural logs of both sides of the equation to obtain

$$\ln Y = \ln \alpha + \beta \ln X - \nu X. \quad (4)$$

This is of the form $Z = \beta_0 + \beta_1 V_1 + \beta_2 V_2$, with $Z = \ln Y$, $\beta_0 = \ln \alpha$, $\beta_1 = \beta$, $V_1 = \ln X$, $\beta_2 = -\nu$, and $V_2 = X$.

The Error Term

The above examples demonstrate how transformations can change nonlinear models into models of linear form. An important *caveat*, however, is that for the correct application of linear estimation theory, the random error term ε must appear as an additive term in the resulting (transformed) linear model and exhibit what may be called *normal sphericity*; that is, the errors for different observations in the linear model must be independent and identically distributed as normal variates from a Gaussian distribution of mean 0 and variance σ^2 . More succinctly, $\varepsilon \sim N(0, \sigma^2)$.

Thus, for example, in the original nonlinear model (1) above, the error should appear in the exponent: $Y = e^{\beta_0 + \beta_1 X_1 + \beta_2 X_2 + \varepsilon}$, as opposed to being added on to the exponentiated expression so that after the ln transformation, the error appears properly in the linear model $\ln Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \varepsilon$. Furthermore, of course, the error term must have the normal sphericity properties. Similarly, for model (3), ε should appear in the exponent $Y = \alpha X^\beta e^{-\nu X + \varepsilon}$ of the original model, suitably distributed, for the transformed linear model to be a candidate for application of linear model least squares theory for analysis. Note, however, that needing the error term to satisfy a certain condition does not constitute a valid reason for assuming this to be the case. The error term actually does satisfy this required condition, or it does not. If it does not, then the model that assumes it does should not be used. The more realistic model should be used, even if this means that it will remain nonlinear even after the transformation.

For example, Model (2), above, the Michaelis–Menten model, usually does not exhibit the correct error structure after transformation and is usually analyzed as a nonlinear model to avoid bias in the analysis, even though the reciprocal transformation yields a tempting linear form. Standard regression residual analysis, including scatterplots and quartile plots, can be used to substantiate appropriate error term behavior in transformed linear models. There are some excellent texts dealing with nonlinear regression models, including material on transforming them to linear models [1–4].

INUS Conditions

The term 'INUS condition' was introduced in 1965 by philosopher John Mackie, in the context of his attempt to provide a logical analysis of the relation of causality in terms of necessary and sufficient conditions [5, 6]. His theory of causation can be seen as a refinement of the theories of D. Hume and of J.S. Mill.

We will start with a rough and provisional statement of Mackie's theory of causality, which we will then look at in some detail. In the course of this, we will have occasion to slightly modify and qualify the rough provisional explication with which we have started until we reach a more detailed and more accurate account. To conclude, the notion of an INUS condition will be related to the methodology of the behavioral sciences.

A Rough Sketch of Mackie's Theory of Causality

C is a cause of E if and only if

1. C and E are both actual
2. C occurs before E
3. C is an INUS condition of E

Here, the notion of an INUS condition is spelled out as follows:

C is an INUS condition of E if and only if C is an **I**nsufficient but **N**onredundant part of a Condition, which is itself **U**nnecessary but exclusively **S**ufficient for E in the circumstances.

The notion of INUS condition is thus the central component of Mackie's theory of causation. We will now explain Mackie's theory of causation in some more detail.

We start with an illustration of what it means for one event to cause another. If we say that a particular flash of lightning was a cause of a forest fire, then both the lightning flash and the forest fire must have occurred, and the occurrence of the lightning flash must have temporally preceded the occurrence of the forest fire. The particular lightning flash is a component of a complex condition, which was, in the circumstances, sufficient for the forest fire to start. This complex condition might, for instance, also contain the dryness of the grass and the fact that when

lightning struck, there was no fire truck driving by. So the lightning flash was not by itself sufficient to start the fire, but conjoined with these other components, it was. Now this complex condition (lightning flash, dry grass, no fire truck) need not be a necessary condition for the forest fire to start. For instance, if there was no lightning flash, but someone had thrown a lighted match in the grass, that might also have set the forest on fire.

This gives us a way to depict the logical structure of the relation of causality. The *full cause* C of an effect E is a disjunction of complex conditions $C_1, \dots, C_n$, where each C_i is a conjunction of positive and negative conditions $(\neg)p_1^i, \dots, (\neg)p_k^i$. So the logical form of a typical full cause C of an effect E could be:

$$(A \wedge B \wedge \neg D) \vee (G \wedge B \wedge \neg D)$$

We can apply this to the example above by setting

1. A = lightning flash
2. B = grass is dry
3. D = there is a fire truck passing
4. G = a lighted match is thrown

The disjuncts of the full cause must contain no nonredundant components. The individual conjuncts of the disjuncts out of which the full cause C of E consists are called the *INUS conditions* of E. So in our example, $\{A, B, \neg D, G\}$ is the collection of INUS conditions of E. The INUS conditions of E can be seen as *possible causes* of E in the *ordinary sense of the word*, for ordinarily, when asked what caused E, we do not give what Mackie calls the *full cause* of E. The actual causes in the ordinary sense of the word are the components of the disjuncts of the full cause that actually obtain. Suppose the disjunct $(A \wedge B \wedge \neg D)$ has occurred. What are called the *actual causes* of E are then the components A, B, $\neg D$ of the disjunct of C that has obtained.

This is the approximate core of Mackie's theory of causality.

Qualifications and Complications

First, Mackie stresses that the account given up to now needs to be put into the perspective of a background context which is assumed to obtain, and which Mackie calls the *causal field* F. To come back

to our example, without oxygen, the forest would not have burned. But it would be strange to call the presence of oxygen a cause of the forest fire, since forests in fact *always* contain oxygen. So it may be taken to be a part of the causal field that the part of the atmosphere where the forest is located contains enough oxygen to allow the burning of the forest. If we take this into account, then the logical form of our example of causality will be:

$$F \rightarrow [((A \wedge B \wedge \neg D) \vee (G \wedge B \wedge \neg D)) \leftrightarrow E] \quad (1)$$

Second, it needs to be stressed that $\rightarrow$ and $\leftrightarrow$ in (1) are not merely material implications, but must be assumed to have *counterfactual strength*. When $\rightarrow$ and $\leftrightarrow$ are read as material implications, (1) only makes a claim about the actual world. But the implicative relations expressed by the formula above are intended to hold also in counterfactual situations. So formula (1) implies, for instance, that in a counterfactual situation in which not the first but the second disjunct $G \wedge B \wedge \neg D$ obtains, E must also obtain.

Let us pause here for a moment to notice a consequence of this. The fact that (1) is assumed to hold in *all* counterfactual circumstances implies that irreducibly *indeterministic causation* cannot be modeled by Mackie's theory, for an indeterministic cause is not required to produce the effect in all counterfactual circumstances (see [7, Chapter 7]). Mackie's theory can, therefore, be no more than a theory of deterministic causation. Also, Mackie's account presupposes that we have a theoretical grip on counterfactual conditionals. However, it has proved to be difficult to construct a satisfactory theory of the logic of counterfactual conditionals. A description and defense of one of the leading theories of counterfactuals is given in [3, 4].

Third, there is a *fourth* condition, which, in addition to the three conditions mentioned in the provisional description of Mackie's account, has to be satisfied for C to be a cause of E. Mackie requires that the disjunct of the full cause of E to which C belongs is the *only* disjunct which is true. The reason for this requirement is that Mackie wants to exclude the possibility of *causal overdetermination*. To come back to our example, imagine the situation in which *both* lightning struck the grass (A) *and* a lighted match was thrown in the grass (G) (and the grass was dry and no fire truck was driving by). In this imagined situation, the fourth condition that we have just sketched is violated. Mackie would say

that *neither A nor G* would count as a cause of E. Many have found this an unwelcome consequence of Mackie's theory. They would say that in the imagined situation, *both* the lighted match *and* the lightning flash are causes of the forest fire. In other words, many authors find causal overdetermination a genuine possibility. (For this reason, we have not included this requirement in the provisional account.) See, for instance, [8].

Fourth, in the provisional statement of Mackie's explication of the causal relation between C and E, we required C to temporarily precede E. Mackie objects to this requirement as we have formulated it since it rules out by fiat the possibility that a cause is simultaneous with its effect, and a fortiori that an effect precedes its cause (*backwards causation*). Mackie wants to leave simultaneous and backwards causation open as a possibility. For this reason, he tries to ensure the asymmetry of the relation of causality by a weaker requirement. For C to cause E, Mackie requires that C is *causally prior* to E. And C is causally prior to E if C is fixed earlier than E is fixed, where a condition C is fixed at a moment t if it is *determined* at t that C will occur. This leaves open the possibility that a condition C at t_2 causes a condition E at t_1 even if $t_1 < t_2$. For, it is possible that it is fixed (or determined) that C will occur *before* it is fixed that E will occur. In this way, the requirement of temporal precedence must be replaced by Mackie's more complicated requirement of causal priority. Note, however, that even in the amended account of Mackie's theory, it is *some* relation of temporal precedence that ensures the asymmetry of causality. A good reference on problems related to backward causation is [2].

Mackie's Theory and Experimental Methods

In most situations, the full cause of an event E that has happened is not known. What we usually have is a list of conditions that may be causally relevant, and the information that one (or some) of them, call this condition A, has occurred immediately before event E. From this information, we can, using Mill's *method of difference*, try to derive that A must be an actual cause of E. Suppose that we have a list $A_1, \dots, A_n$ of factors that are thought to be causally relevant. Then we can investigate which

factors are present whenever the event E occurs and which factors are absent whenever E occurs. This information can then be gathered into disjunction of conjunctions of conditions, which may give us the full cause of E. Even if it does not, this information may tell us that A is an INUS condition of E. And, even if that is not the case, the information obtained from the method of difference may strengthen our belief that A is an INUS condition of E.

Mackie's theory can also be related to statistical testing procedures (see **Classical Statistical Inference: Practice versus Presentation**). Suppose we do the following experiment (see also [1, p. 210 ff]). A random sample of laboratory rats is randomly divided into an experimental group and a control group. The experimental group is put on a diet that contains 5% saccharin. The control group receives the same diet, minus the saccharin. When a rat dies, we check whether it has developed bladder cancer. After two years, the remaining rats are killed and examined. We observe that the fraction of animals with bladder cancer is higher in the experimental group. The difference is statistically significant, so we conclude that saccharin consumption is positively causally relevant for bladder cancer in populations of laboratory rats. In other words, we conclude that, in a population where all rats would consume saccharin (this hypothetical population is represented in the experiment by the experimental group), there would be more bladder cancers than in a population without saccharin consumption.

If we claim that smoking is positively causally relevant for lung cancer in the Belgian population, we make a similar counterfactual claim. In Belgium, some people smoke, others do not. Positive causal relevance means that, if every Belgian would smoke (while their other characteristics remained the same), there would be more instances of lung cancer than in the hypothetical population where no Belgian smokes (while their other characteristics are preserved). INUS conditions provide a framework for interpreting such claims about causal relevance in populations. Since not all rats that consume saccharin develop bladder cancer, it is plausible to assume that there is at least one set of properties X such that all rats which have X and consume saccharin develop bladder cancer. In fact, there may be several such properties, which we denote as $X_1, \dots, X_m$. This means that experiments like the one described above can be

seen as methods for establishing that something (e.g., saccharin consumption) is an INUS condition without having to spell out what the other components of the conjunct are. We show that there is at least one X such that $X \wedge C$ is a sufficient cause of E, but we do not know (and do not need to know) what this X is.

We have been cautious in our formulations in the previous paragraph ('it is plausible' and 'can be seen'). The reason for this is that interpreting causal hypotheses about populations in the indicated way assumes that the individuals that constitute the populations are deterministic systems. It is equally plausible to assume that there is also indeterminism at the individual level. But as was mentioned above, Mackie's theory of causation is a conceptual framework for developing deterministic interpretations of experimental results. This means that it is incomplete: we need a complementary framework for developing genuinely indeterministic interpretations.

Finally, a brief remark on the notion of a causal field. The causal hypotheses we considered were hypotheses about populations. If we interpret the claim along the lines of Mackie, the characteristics of the population (e.g., the properties that all rats have in common) constitute the causal field. So also the notion of a causal field has its counterpart in experimental practice.

Item Analysis

Item analysis is a fundamental psychometric activity that impacts both test construction and scoring.¹ Within the test construction process, it supplements the qualitative evaluation of item content and presentation format that item writers and test editors carry out, providing a focused, quantitative analysis of every test item to determine whether each is at an appropriate level of difficulty and exhibits adequate information to distinguish among examinees at different proficiency levels. As part of the test scoring process, item analysis can statistically verify the correctness of answer keys and scoring rules, aid in identifying flawed or ambiguous items, and help to determine if any items are potentially biased or otherwise problematic for certain subgroups in the population.

This entry has two sections. The first section covers the primary components used in scoring test items and highlights some similarities and differences between different item types. The second section illustrates some of the common statistics and presentation formats used in item analysis.

Scoring Expressions and Scoring Evaluators

Item analysis for paper-and-pencil multiple-choice (MC) tests is covered in most textbooks about testing and measurement theory (e.g., see references [1, 2, 6, 7] and [13]). However, traditional MC item analysis methods have not been readily extended to the growing variety of item types used on modern tests. The intent in this section is to present a structured framework, based on modern database concepts, for understanding scoring mechanisms applicable to a wide variety of item types. The framework provides the basis for discussing item analysis methods in the final section.

Classes of Item Types

In developing a framework for item analysis, it is almost imperative to consider some of the similarities among the different item types. Most item types actually fall into one of two broad classes: (a) selected-response items and (b) constructed-response items.

These item type classes do share some common data components that can be exploited.

Selected-response (SR) items include binary response items such as true-false or alternate-choice items, multiple-choice (MC) items with one-best answer, multiple-choice items with two or more best answers, and matching items that require the test taker to match the elements of two or more lists (see [8] and [13]). **Computer based testing** (CBT) has further expanded the array of selected-response item types, adding functional descriptions like *hot-spot* items, *drag-and-drop* items, *build-list-and-reorder* items, and *create-a-tree* items (e.g., [12]). Despite some of their apparent surface differences, virtually all SR item types have two common features: (a) a fixed list of alternative answer choices – often called the *answer options* or *distractors* and (b) a response-capturing mechanism that determines how the test taker must select his or her response(s) from the list of choices (e.g., filling in a ‘bubble’ on an answer sheet, using a computer mouse to click on a ‘radio button’ option, using a computer mouse to drag a line connector to indicate a relationship between two network objects).

Constructed-response (CR) items provide the examinee with prompts or sets of task directives. The examinees must respond using some type of response-capturing mechanism that can range from fill-in-the-blank fields on an answer sheet or in a test booklet to a large collection of computer software *controls* such as input boxes, text editors, spreadsheets, and interactive applications that record what the examinee does or that yield a complex performance-based work-sample. The prompts or task directives and the response-capturing mechanism may constrain the nature of the responses. However, unlike SR items, CR items do not incorporate fixed lists of alternatives from which the examinee chooses his or her answer. Therefore, examinees can produce an enormous number of possible responses.

A Framework for Scoring and Analysis of SR and CR Items

Both SR and CR items can be scored and analyzed under a broad item analysis framework by developing a system that includes three components: (a) scoring expressions; (b) scoring evaluators; and (c) a scoring expression database. These components readily generalize to most item types.

2 Item Analysis

A *scoring expression* is a type of scoring rule that converts the test taker's response(s) into a point value – usually zero or one. A *scoring evaluator* is a computer software procedure that performs a specific comparative or evaluative task. *Scoring evaluators* can range from simple pattern matching algorithms to complex analytical algorithms capable of evaluating essays and constructed responses.² A *scoring database* is where the answers and other score-related data are stored until needed by the scoring evaluator.

A scoring expression used by a scoring evaluator takes the form

$$y_i = f(r_i, a_i) \quad (1)$$

where r_i is the response set provided by the examinee and a_i is an answer key or set of answer keys. Selected-response items can directly use this type of scoring expression. For example, a conventional MC item has three to five distractors, a response-capturing mechanism that allows the examinee to select only one answer from the list of available distractors. Consider a multiple-choice item with five options, 'A' to 'E'. The examinee selects option 'B', which happens to be the correct answer. Using (1) to represent a simple pattern matching algorithm, the scoring rule would resolve to $y = 1$ if $r = a$ or $y = 0$ otherwise. In this example, $r = 'B'$ (the examinee selected 'B') and $a = 'B'$ (the answer key), so the item score resolves to $y = 1$ (correct). If r is any other value, $y = 0$ (incorrect). More complicated scoring rules may require more sophisticated scoring evaluators that are capable of resolving complex logical comparisons involving conjunctive rules such as $a = 'A \text{ AND NOT}(B \text{ OR } C)'$, or response ordering sequences such as $a = 'Object 7 \text{ before Object } 4'$. As Luecht [12] noted, when the examinee's response involves multiple selections from the list of options, the number of potential scoring expressions can grow extremely large. That is, given m choices with k response selections allowed for a given item, there are

$$C_k^m = \frac{m!}{k!(m-k)!} \quad (2)$$

possible combinations of responses, r_i , of which, only a subset will comprise the correct answers.

There are numerous types of scoring mechanisms and scoring rubrics employed with CR items. The scoring evaluators can employ simple matching

algorithms that compare the test taker's response to an idealized answer set of responses. Analytical scoring evaluators – sometimes called *automated scoring* when applied to essays or performance assessments (e.g., see references [3, 4] and [5]) – typically break-down and reformat the test taker's responses into a set of data components that can be automatically scored by a computer algorithm. The scoring algorithms are applied to the reformatted responses and may range from weighted functions of the scorable data components, based upon Boolean logic, to self-learning neural nets. Holistic scoring rubrics, typically used by trained human raters evaluating essays or written communications, outline specific aspects of performance at ordered levels of proficiency and may state specific rules for assigning points.

A scoring function for CR items is

$$y_i = f[g(r_i), h(a_i, r_{i-1})] \quad (3)$$

where $g(r_i)$ denotes a transformation of the original examinee's responses into a scorable format (e.g., extracting the entry in a spreadsheet cell or converting a parsed segment of text into a given grammatical or semantic structure), and where $h(a_i, r_{i-1})$ is an embedded answer processing function that may involve consideration of prior responses. For example, suppose that we wish to allow the examinee's computations or decisions to be used resolving subsequent answers.³ In that case, $h(a_i, r_{i-1})$ might involve some auxiliary computations using the prior responses, r_{i-1} , provided by the examinee, along with the computational formulas and other values embodied in a_i . When no prior responses are considered, the scoring expression (3) simplifies to

$$y_i = f[g(r_i), a_i]. \quad (4)$$

When no transformation of the examinee's responses is performed, the scoring expression simplifies to (1).

As noted earlier, the scoring expressions must be stored in a *scoring expression database*. Each item may have one or more scoring expression records in the database. The scoring records identify the item associated with each scoring expression, the scoring answers, arguments, rules, or other data needed to evaluate responses, and finally, reference to a scoring evaluator (explained below).

ItemID	ExpressionID	Answers	Evaluator	Value
ITM001	EXPR000001	ANS = "B"	SPM	1
ITM002	EXPR000005	ANS = "A" AND ANS = "E"	CPM	1
ITM003	EXPR000011	ANS = "945.3"; TOLER = "0.01"	SMC	1

Figure 1 A scoring expression database for three items

In special cases, programmed scripts can be incorporated as part of the data. In general, it is preferable to store as much scoring information as possible in a structured database to facilitate changes.

Figure 1 presents a simple database table for three items: ITM0001, ITM002, and ITM003. ITM001 is a one-best answer MC item where 'B' is the correct answer. ITM002 is a multiple-selection SR item with two correct answers, 'A' and 'E'. Finally, ITM003 is a CR item that requires the examinee to enter a value that is compared to a target answer, 945.3 within a prescribed numerical tolerance, ± 0.01 . Three scoring evaluators are referenced in Figure 1: (a) a simple pattern-match (SPM) evaluator for performing exact text matches such as $r_i = a_i$; (b) a complex pattern-match (CPM) evaluator that compares a vector of responses, $\mathbf{r}_i$, to a vector of answers, $\mathbf{a}_i$, using Boolean logic; and (c) a simple math compare (SMC) evaluator that numerically compares r_i to a_i , within the prescribed tolerance (TOLER). More advanced scoring evaluator might compare the ordering of selected objects or perform very complex analyses of the responses using customized scripts to process

the data. A thorough discussion of scoring evaluators is beyond the scope of this entry.

A special class of scoring expressions is *auxiliary-scoring expressions* (ASE). Their primary use is to facilitate the item analysis. For SR items, auxiliary-scoring expressions represent all possible response options other than the primary answer key(s). The item analysis procedures evaluate whether the examinee's response 'hits' on one of these auxiliary-scoring expressions (i.e., the ASE Boolean logic is *true*). For example, the four *incorrect* response options associated with a five-choice, one-best answer MC item would each constitute an auxiliary-scoring expression. Anytime an examinee selects or enters data that matches the conditions of the scoring expression, there is a 'hit' on that scoring expression. An analysis of the 'hits' on the auxiliary-scoring expressions for each item is identical to conducting a distractor analysis. These auxiliary expressions can suggest alternative correct answers or might hint at the actual correct answer for a miskeyed MC item. The auxiliary-scoring expressions can be predetermined for SR items since the list of alternative responses is known in advance. For CR items, they may need

ItemID	ExpressionID	Status	Answers	Evaluator	Value
ITM001	EXPR000000	PAK	ANS = "B"	SPM	1
ITM001	EXPR000001	ASE	ANS = "A"	SPM	0
ITM001	EXPR000002	ASE	ANS = "C"	SPM	0
ITM001	EXPR000003	ASE	ANS = "D"	SPM	0
ITM001	EXPR000004	ASE	ANS = "E"	SPM	0
ITM002	EXPR000005	PAK	ANS = "A" AND ANS = "E"	CPM	1
ITM002	EXPR000006	ASE	ANS = "A" AND NOT (ANS = "E")	CPM	0
ITM002	EXPR000007	ASE	ANS = "E" AND NOT (ANS = "A")	CPM	0
ITM002	EXPR000008	ASE	ANS = "B"	CPM	0
ITM002	EXPR000009	ASE	ANS = "C"	CPM	0
ITM002	EXPR000010	ASE	ANS = "D"	CPM	0
ITM003	EXPR000011	PAK	ANS = "945.3"; TOLER = "0.01"	SMC	1
